Mitosis in Animal Cells

ATY Lian and M Chircop, Children's Medical Research Institute, Westmead, NSW, Australia and University of Sydney, Sydney, NSW, Australia

Introduction

Mitosis is the final phase of the cell cycle (Figure 1). It is a relatively short phase. For example, mitosis occupies approximately 10% of the total cell cycle time of a typical human proliferative cell (Alberts, 2002). Mitosis is the division process of the cell cycle whereby the duplicated chromosomes and cytoplasmic organelles are separated into two independent daughter cells (Nurse, 2000). As shown in Figure 2, this process is easily visible by conventional light microscopy. Interphase makes up the remainder of the cell cycle and proceeds mitosis. It consists of G1, S (synthesis), and G2 phases, whereby the chromosomes and centrosomes are duplicated during S phase.

Thus, interphase prepares the cell for division. Centrosomes are the microtubule organizing centers of the cell and are duplicated and divided in a cycle that is tightly coupled to the cell cycle (Figure 1). Its duplication is essential for equal segregation of the duplicated chromosomes as the centrosomes form the poles of the mitotic spindle. Mitosis only occurs in eukaryotic cells and this process differs amongst specific groups. For example, animal cells undergo an 'open' mitosis – nuclear envelope breaks down prior to chromosome segregation. Whereas fungi such as *Aspergillus nidulans* and *Saccharomyces cerevisiae* (yeast) undergo a 'closed' mitosis – chromosomes divide within an intact nucleus.

Mitosis is a highly complex process consisting of six distinct sequential stages – prophase, prometaphase, metaphase,

Figure 1 The animal cell cycle. The animal cell cycle is made up of four phases: (1) G1 phase, where cellular contents are duplicated; (2) S phase, where chromosomes are replicated; (3) G2 phase, where the cell ensures proper DNA replication; and (4) M phase (mitosis), where the cell is physically separated into two daughter cells. Together, G1, S, G2 phases are also known as interphase. The cell in G1 phase can enter into G0 phase, a quiescent phase. Cell cycle progression is tightly regulated by a series of checkpoint mechanisms that delay progression until errors are corrected. After completion of mitosis, the cell reenters G1, ready for the next cycle. The cell cycle is tightly coordinated with the centrosome cycle. A centrosome contains a mother centriole and a daughter centriole (dark green). The mother centriole is distinguishable by its additional distal appendages. The centrosomes are surrounded by the PCM (pink). The centrosomes are separated in late G1/early S phase in preparation of duplication, followed by the formation of procentrioles (daughter centrioles) at the proximal ends (light green). The procentrioles continue to elongate during S and G2 phases and reach maturity in late G2 phase. Centrosome separation occurs during mitosis and upon completion, each daughter cell inherits one centrosome.

Figure 2 The multiple stages of mitosis. Mitosis begins with prophase where chromatin condenses into chromosomes (purple). The nuclear envelope breaks down in prometaphase and duplicated centrosomes move to the opposite poles of the cell. During metaphase, paired sister chromatids attach to the microtubules (green) from opposite poles at the centromere and align at the equatorial plane. The sister chromatids are separated and pulled toward opposite poles during anaphase. During telophase, a new nuclear envelope starts to form around each set of the separated sister chromatids and they condense and unfold back into the chromatin. Cytokinesis heavily overlaps with late anaphase and early telophase and requires two events: membrane ingression and membrane abscission. The formation of the actin–myosin II contractile ring begins in early telophase and its contraction triggers membrane ingression, forming the cleavage furrow. The furrow is fully ingressed in late telophase and the spindle midzone is compressed into a thin intercellular bridge with a protein-dense midbody ring in the center. Cytokinesis is completed when abscission physically splits daughter cells apart.

anaphase, telophase, and cytokinesis (**Figure 2**). Mitotic progression is highly regulated and involves dynamic modulation of the actin cytoskeleton, microtubule network (formation of mitotic spindle), as well as membranes to align and then equally segregate the genome and cytoplasmic contents into two daughter cells. Protein kinases play a pivotal role in executing cell division. The major protein kinases that mediate key mitotic events include the serine/threonine protein kinases, cyclin-dependent kinases (Cdks) whose catalytic activities are dependent on their regulatory cyclin subunits, polo and polo-like kinases (Plk), Aurora kinases, Nek (NIMA-related kinase), and Bub families, as well as Greatwall and Mps1/TTK ([Ma and Poon, 2011](#)). Spatial and temporal activation of protein kinases is essential for regulating centrosome maturation and separation, formation of the bipolar mitotic spindle, chromosome capture (microtubule–kinetochore attachment), sister chromatid segregation, and cytokinesis. Thus ensuring mitosis proceeds in an ordered manner and completes successfully, protecting cells against genetic instability during cell division. The key events

that occur at each stage of mitosis and those molecular components involved as well as how they are regulated in animal cells, specifically by protein kinases, are discussed.

Stages of Mitosis

Prophase

Prophase is characterized morphologically by profound changes in the cell's architecture to detach from the substrate and become round in shape as well as condensation of chromatin into chromosomes. Cell rounding involves extensive rearrangement of the actin cytoskeleton, de-adhesion, and an increase in cortical rigidity ([Dao et al., 2009](#); [Kunda et al., 2008](#)). It is important for subsequent mitotic events such as spindle assembly and positioning as well as chromosome capture. During this time, the two sister chromatids from the replicated chromosomes are bound together at the centromere

by a protein complex known as cohesin. Time-lapse microscopy analysis of HeLa cells reveals that cell rounding is one of the earliest mitotic events in prophase occurring prior to centrosome separation and visible chromatin condensation followed by nuclear envelope breakdown (NEB) (Matthews *et al.*, 2012). Cell rounding as well as cortical stiffening is primarily driven by the small GTPase RhoA, which is activated upon mitotic entry (Maddox and Burridge, 2003; Matthews *et al.*, 2012) and concentrates at the cell cortex (Mali *et al.*, 2010; Matthews *et al.*, 2012). RhoA is regulated by the Cdk1/cyclin B1 protein kinase, which phosphorylates the RhoA regulators, the guanine exchange factor (GEF) Ect2 (Hara *et al.*, 2006; Matthews *et al.*, 2012; Niiya *et al.*, 2006), and the GTPase activating protein (GAP) p190RhoGAP (Maddox and Burridge, 2003). The result is a global increase in RhoA activity (Maddox and Burridge, 2003). Active RhoA mediates cell rounding and cortical stiffening through activation of its downstream effectors, Rho kinase (ROCK) and subsequent phosphorylation of myosin II in an analogous pathway for contractile ring assembly and function during the ingression phase of cytokinesis (Maddox and Burridge, 2003; Matthews *et al.*, 2012).

Prior to separation, centrosomes undergo maturation, which is executed by Plk1. Centrosomes consist of two perpendicularly orientated centrioles that are surrounded by pericentriolar material (PCM; Figure 1). Plk1 phosphorylates the PCM component, pericentrin (Lee and Rhee, 2011a), which subsequently recruits additional PCM components to coordinate microtubule nucleation for mitotic spindle assembly (Lee and Rhee, 2011b). Following centrosome maturation, the two centrosomes dissociate and move to opposite ends of the cell, forming the poles of the mitotic spindle (Meraldi and Nigg, 2002). At the spindle poles, nucleated microtubules originating from the centrosomes are organized into dense, radial arrays over the nuclear envelope. The end of prophase corresponds to NEB and again this is thought to be triggered by Cdk1/cyclin B1 (Lindqvist *et al.*, 2009) as well as Cdk1/cyclin A2 (Gong *et al.*, 2007).

Prometaphase

Prometaphase begins when the nuclear envelope disassembles, exposing nuclear structures and its contents to the cytoplasm. The nuclear envelope is composed of two membrane barriers, the inner nuclear membrane (INM) and the outer nuclear membrane (ONM). The nuclear envelope is stabilized by nuclear lamina (polymerization of lamin proteins) underlying the INM. NEB is thought to involve early spindle microtubules directly piercing the nuclear envelope causing folds and invaginations that create mechanical tension in the nuclear lamina (Beaudouin *et al.*, 2002; Georgatos *et al.*, 1997). Lamins are subsequently phosphorylated by Cdk1/cyclin B1 triggering their depolymerization, causing the nuclear envelope to vesiculate (Gallant and Nigg, 1992; Heald and McKeon, 1990; Peter *et al.*, 1990). Concurrently, nuclear pore complexes (NPCs) are disassembled by phosphorylation of the core components, nucleoporins, resulting in complete dissolve of the membrane permeability barrier (Terasaki *et al.*, 2001).

Following NEB, the mitotic spindle is assembled for alignment of chromosomes along the center of the cell

(metaphase plate) and subsequent equal segregation of sister chromatids (anaphase) into daughter cells (Helmke *et al.*, 2013; Rieder, 2005). The mitotic spindle is a bipolar structure composed of microtubules and associated motor proteins. Microtubules initially emanate from the spindle poles/centrosomes toward the cell equator and with their plus-ends attach to a large protein assembly on the centrometric chromatin of a chromosome called the kinetochore (Figure 3). This population of microtubules is termed kinetochore- or K-fibres. This attachment allows rapid movement of the bound chromosome such that the sister kinetochore attaches to a microtubule growing from the opposing centrosome. The result is a correctly bi-orientated chromosome at the metaphase plate with a stable microtubule–kinetochore attachment. Once all chromosomes have achieved this, the cell is considered to be in metaphase and chromosome segregation during anaphase can proceed. The mitotic spindle consists of two other populations of microtubules: (1) microtubules that do not attach to kinetochores, but also emanate toward the cell center and are called central spindle or non-kinetochore microtubules and (2) microtubules that emanate from the centrosomes circumferentially and anchor at the cell cortex are called astral microtubules, which function to maintain correct spindle orientation. Proteomics of purified mitotic spindles has identified approximately 800 spindle-associated proteins (Sauer *et al.*, 2005), indicating the breadth of signaling pathways required to establish and maintain this structure for correct chromosome attachment and alignment. Future investigation of these proteins in functional studies will aid in our understanding.

Metaphase

Metaphase is typified by the alignment of chromosomes at the center of cell, commonly referred to as the metaphase plate. The chromosomes are now highly coiled and condensed. The kinetochore microtubules from opposing spindle poles capture each pair of sister chromatids at their kinetochores so that the chromosomes are attached in a bi-orientated manner. During this capture process, the chromosomes oscillate gently at the metaphase plate due to the pulling forces and tension across sister kinetochores that are generated by the kinetochore microtubules. The signal for chromosome separation/segregation is governed by the spindle assembly checkpoint (SAC; Box 1; Figure 4). Premature or aberrant chromosome segregation results in aneuploidy, and is avoided by activity of the SAC. This signaling pathway consists of a number of protein complexes that monitor mitotic spindle assembly, delaying anaphase onset until all chromosomes have formed stable bipolar attachments to the spindle via kinetochores (Musacchio and Salmon, 2007).

Astral microtubules play a key role during metaphase by regulating spindle stability and orientation. Spindle orientation is achieved through signaling pathways that link the plus-ends of astral microtubules to the cell cortex (Kotak and Gonczy, 2013). The core machinery necessary for spindle orientation has been identified in most cell contexts (*Caenorhabditis elegans*, *Drosophila*, and cultured mammalian cells) and involves four components (Bergstrahl *et al.*, 2013; Kotak and Gonczy, 2013). In human cells, this includes the

Figure 3 The centromere–kinetochore association. The centromere is composed of borealin, survivin, Aurora B, inner centromere protein (INCENP), and mitotic centromere-associated kinesin (MCAK), which function to regulate stability of microtubule–kinetochore attachments. The kinetochore is a protein matrix attached to the centromere and is composed of several layers (Musacchio and Salmon, 2007). The inner plate is in contact with the centromere (or centromeric DNA) and is marked by the specialized histone variant CENP-A (which substitutes histone H3 in this region) as well as additional auxiliary proteins. Adjacent to the inner plate is the outer plate, which consists primarily of proteins that assemble at the kinetochore upon NEB. Evolutionarily conserved proteins such as Spc105, MIS12, MSM21, and Hdc80 occupy this space to form attachment sites for bundles of microtubules known as K-fibers. In animal cells, kinetochores contain approximately 20 anchoring sites for the plus-ends of microtubules. The outer most region of the kinetochore is the fibrous corona and consists of proteins that are highly dynamic in their concentration. These proteins are either high in their concentration at the kinetochore before (molecular motors CENP-E and dynein as well as their target components ZW10 and ROD, and the spindle checkpoint proteins such as Mad1, Mad2, BubR1, and Cdc20) or after (EB1, APC, and proteins in the Ran pathway such as RanGap1 and RanBP2) K-fiber capture.

motor protein dynein, which is cortically anchored by an evolutionary conserved ternary protein complex consisting of G-protein signaling modulator-2 (LGN), nuclear mitotic apparatus (NuMA), and Gai (Kotak and Gonczy, 2013). Gai binds to the plasma membrane and this may involve the GEF, Ric8 (Woodard *et al.*, 2010). GDP-bound Gai recruits and anchors LGN at the cell cortex by binding to its C-terminal GoLoCo motifs. The N-terminal TPR domains of LGN forms a docking platform for NuMA. NuMA associates with minus-end-directed microtubule motor, dynein via its N-terminus. The LGN-dynein interaction is specific to the cortically localized dynein as the depletion of LGN does not disrupt other pools of dynein on kinetochore or spindle microtubules (Kiyomitsu and Cheeseman, 2013). Collectively, this complex functions in spindle-capture as well as in force generation, whereby it is hypothesized that dynein attempts to move along astral microtubules toward the spindle poles, but instead pulls on the astral microtubules, generating tension (Hendricks *et al.*, 2012; Laan *et al.*, 2012). Disruption of the ternary complex alters cortical dynein levels and thus spindle positioning (Kotak *et al.*, 2012; Zheng *et al.*, 2013).

Anaphase

The separation of sister chromatids marks the commencement of anaphase followed by the movement of chromosomes toward the spindle poles. The chromosomes are pulled apart by shortening of the kinetochore microtubules at the centromere attachment sites, and this is thought to be triggered by the loss of tension following cleavage of the cohesin complex. Simultaneously, the non-kinetochore spindle microtubules elongate, thereby pushing the centrosomes farther apart. This is regulated by two forces: (1) plus-end-directed motor

proteins, such as end-binding protein-1 (EB1), at the central spindle and between the overlapping microtubules from both poles (Tamura and Draviam, 2012). These motor proteins slide the microtubules at the plus-ends past one another, creating the forces to push the spindle poles farther apart. (2) Minus-end directed motor proteins, such as dynein, that interact with the cell cortex and the astral microtubules to create pulling forces on the spindle poles (Tamura and Draviam, 2012). By the end of anaphase, the kinetochore microtubules have disassembled and a complete set of chromosomes has assembled at each pole and begun to decondense. During this time, cyclin B1 is degraded, resulting in the inactivation of Cdk1 and this is necessary for driving mitotic exit (Hershko, 1999).

Telophase

During telophase, the cell continues to elongate due to lengthening of the microtubules. The chromosomes at both poles begin to uncoil and the nuclear membrane vesicles (disassembled in prophase) reform the nuclear envelope around each set of chromosomes, forming two daughter interphase nuclei. The membrane at the cell equator also begins to fold into the cell, forming an ingression furrow that results in compression of the central spindle.

Cytokinesis

Cytokinesis is the final stage of cell division that generates two independent daughter cells and is often the longest stage of cell division. Cytokinesis in animal cells can be subdivided broadly into two steps: (1) membrane ingression and (2) membrane abscission (Figure 2; Glotzer, 2005). These steps

Box 1 The spindle assembly checkpoint

The 'spindle assembly checkpoint' or SAC is a term used to describe the complexes of proteins and signaling pathways that prevent anaphase onset until all chromosomes have achieved bi-oriented attachment via their kinetochores to the mitotic spindle and are aligned at the metaphase plate (**Figure 4**). As such, the SAC is activated upon mitotic entry due to the presence of unattached kinetochores. In addition to microtubule–kinetochore attachment, tension is also important for SAC inactivation (*Nicklas et al., 1995*). Microtubule–kinetochore tension is initially low but high upon bi-orient attachment resulting in an increase in kinetochore-to-kinetochore distance between sister chromatids, which ultimately aids in their segregation during anaphase. Incorrectly attached chromosomes have low tension and this is detected by Aurora B (Ipl1 in *Saccharomyces cerevisiae*) kinase (*Tanaka et al., 2002*). Cells that have an impaired SAC enter anaphase prematurely and are genomically unstable.

The core SAC signaling components reside at the kinetochore (**Figure 3**). Many of these proteins localize to unattached kinetochores in prometaphase and are removed immediately following attachment of microtubule plus-ends, indicating that events at the kinetochores contribute to SAC activity (*Lara-Gonzalez et al., 2012*). This decrease in protein localization at kinetochores as more attachment sites bind to K-fibres is called occupancy. For example, MAD2 kinetochore localization is reduced at metaphase kinetochores by 50–100-fold compared with unattached prometaphase kinetochores. The SAC targets CDC20, a cofactor of the ubiquitin ligase anaphase-promoting complex/cyclosome (APC/C) (*Hwang et al., 1998; Kim et al., 1998*). Specifically, the SAC negatively regulates the ability of CDC20 to activate APC/C-mediated polyubiquitylation of two key substrates, cyclin B1 and securin, thereby preventing their destruction by the 26S proteasome. Separase cleaves the cohesin complex that holds sister chromatids together, which is required to execute anaphase, whilst cyclin B1 proteolysis inactivates the mitotic kinase, Cdk1, which promotes exit from mitosis (*Peters, 2006*). A mitotic checkpoint complex (MCC) is a SAC effector that contains three SAC proteins, MAD2, the protein kinase BUBR1/Mad3, and BUB3, as well as CDC20 itself (*Sudakin et al., 2001*). The MCC binds the APC/C rendering it inactive. Other 'core' SAC components include MAD1 and the kinases BUB1, multipolar spindle-1 (MPS1), and Aurora B. These proteins are required to amplify the SAC signal and the rate of MCC formation (*Morrow et al., 2005*). Additional proteins that regulate SAC activity in higher eukaryotes include the ROD (rough deal)–ZW10 (zeste white-10)–ZWILCH (RZZ) complex, p31^{comet}, several protein kinases including mitogen activated protein kinase (MAPK), Cdk1/cyclin B1, NEK2, and PIK1; the MT motors centromere protein (CENP)-E (also known as kinesin-7) and dynein; and dynein-associated proteins such as dynactin, cytoplasmic linker protein (CLIP)170, and lissencephaly-1 (LIS1) (*Musacchio and Salmon, 2007*).

are highly ordered processes that begin immediately following chromosome segregation (anaphase) and need to occur in a sequential manner for cytokinesis to be executed correctly. Cytokinesis failure can occur at any one of the steps in this process due to an array of errors such as protein mislocalization, deregulated protein phosphorylation, and erroneous signaling. Depending on the stage of cytokinesis that the error occurs, membrane ingression may not be initiated, or if

partially completed will regress or if the midbody has formed then the nascent daughter cells may remain connected due to persistent bridge formation. Nevertheless, the resultant outcome is the generation of a binucleated (or aneuploid cell), which can lead to genomic instability and thus contribute to the initiation or progression of tumorigenesis.

Membrane ingression

Membrane ingression involves two phases. Firstly, the site of division is determined by recruitment of RhoA. Secondly, the membrane ingresses, which requires the assembly and activity of the actin–myosin II contractile ring (**Figure 5; Glotzer, 2005**).

Immediately after chromosome segregation, cells must ensure that the spindle poles are on opposing sides of the division plane so that the segregated chromosomes are equally distributed into each of the two newly forming cells. In animal cells, the division plane is determined at the metaphase to anaphase transition and its position is dictated in part by signaling pathways mediated by three separate pools of microtubules that collectively form the mitotic spindle (*Burgess and Chang, 2005; Glotzer, 2004*): (1) polar astral microtubules (emanating from the spindle pole to sites away from the ingression site – most likely aid in positioning of the ingression site by inhibiting cortical contraction (*Danowski, 1989; Pletjushkina et al., 2001; Ren et al., 1999*) by spatially regulating myosin recruitment) (*Canman and Bement, 1997; Werner et al., 2007*), (2) equatorial astral microtubules (emanating from the spindle poles toward the ingression site – are thought to contribute to stabilization of the equatorial cortical region (*Canman et al., 2003*), as well as provide positive signals that stimulate formation and contraction for membrane ingression) (*Rappaport, 1986*), and (3) central spindle (a set of antiparallel microtubule bundles between the spindle poles – deliver positive signals to the midzone region, which are especially important for later cytokinetic stages). The roles of each microtubule population are partly redundant but collectively they ensure that a robust division site is established (*Bringmann and Hyman, 2005; Dechant and Glotzer, 2003*).

The key molecule that defines the site to initiate formation of the ingressing furrow in animal cells is active RhoA (*Drechsel et al., 1997; Jantsch-Plunger et al., 2000; Kamijo et al., 2006; Kishi et al., 1993; Piekny et al., 2005*). Its activation is spatially restricted to the equatorial cell cortex as disruption of this restricted spatial regulation results in a wider zone of activation and failure to initiate membrane ingression (*Yuce et al., 2005*). Central spindle microtubules are critical in assembling a signaling network to activate RhoA in a restricted spatially narrow zone at the equatorial cell cortex upon anaphase onset (*Bement et al., 2005; Nishimura and Yonemura, 2006; Yonemura et al., 2004; Yoshizaki et al., 2003; Yuce et al., 2005*). The central spindle components include protein regulator of cytokinesis-1 (PRC1), kinesin-4 family member (KIF4), the centralspindlin complex (composed of kinesin-6 family member MKLP1 and the Rho GTPase activating protein MgcRacGAP) and the chromosomal passenger complex (CPC, composed of Aurora B kinase and its regulatory subunits inner centromere protein INCENP, Survivin, and Borealin) (*Gassmann et al., 2004; Kurasawa et al., 2004;*

Figure 4 SAC signaling and inhibition of the APC/C. During prometaphase, the SAC is activated due to the presence of unattached kinetochores. Mad2 is activated together with BubR1 and Bub3 bind to Cdc20, thereby inhibiting the activity of the APC/C. In metaphase, following correct bi-orient attachment of all chromosomes to the kinetochore microtubules and alignment at the metaphase plate, the SAC is deactivated. This involves release of Mad2, BubR1, and Bub3 from Cdc20, allowing it to activate the APC/C. APC/C subsequently mediates the polyubiquitination of many substrates leading to their degradation. The two key substrates include cyclin B1, to deactivate Cdk1 for mitotic exit, and securin, which releases separase to cleave the cohesin complex that binds sister chromatids. Sister chromatids are now no longer tethered together, leading to their separation during anaphase.

Mishima *et al.*, 2002, 2004; Mollinari *et al.*, 2002; Severson *et al.*, 2000; van der Waal *et al.*, 2012; Wheatley *et al.*, 2001; Zhu and Jiang, 2005). PRC1 is localized at the central spindle, where it interacts and recruits KIF4 (Kurasawa *et al.*, 2004; Zhu and Jiang, 2005). The CPC then phosphorylates MKLP1 and promotes the recruitment of the centralspindlin complex to the central spindle (Douglas *et al.*, 2010; Guse *et al.*, 2005). The centralspindlin component MgcRacGAP together with the RhoGEF, Ect2, contribute to the equatorial activation of RhoA (Kamijo *et al.*, 2006), which subsequently drives assembly and activity of the contractile ring (Figure 5).

The contractile ring drives membrane ingression and invagination of the cell membrane. It is composed of parallel filaments of actin and non-muscle myosin II (Maupin and Pollard, 1986). Myosin comprises two heavy chains, two essential light chains and two regulatory myosin light chains

(MLC). Phosphorylation of MLC on T18 and S19 releases myosin II from an autoinhibitory state, allowing myosin II to assemble into filaments (Ikebe *et al.*, 1988) and subsequently triggering activity of the myosin II motor (Komatsu *et al.*, 2000; Yamakita *et al.*, 1994). Myosin filaments then interact with actin filaments, where it is thought to either cross-link actin filaments or accelerate actin disassembly and together, the contractile ring constricts and the membrane ingresses (Guha *et al.*, 2005; Ma *et al.*, 2012b; Murthy and Wadsworth, 2005; Scholey *et al.*, 1980). The membrane continues to ingress as the contractile ring constricts to its fullest extent, whereby the antiparallel microtubules forming the mitotic spindle (midzone) and associated proteins are compressed to form an intracellular bridge that is approximately 1–1.5 μm in diameter between nascent daughter cells (Eggert *et al.*, 2006). The midzone plays a key role in maintaining the segregated

Figure 5 Membrane ingression is driven by RhoA-mediated signaling pathways. Upon anaphase onset, the site of the division plane is established and RhoA is activated within a narrow zone of the cell cortex. Here, RhoA activates the effectors, mDia1 for unbranched linear actin filament polymerization (Li and Higgs, 2003), as well as the kinases, myosin regulatory light chain kinase (MLCK), ROCK, and citron kinase, to activate myosin II. Myosin II activity is also regulated in part by myosin phosphatase (MYPT1), which down-regulates myosin II contractility by dephosphorylating S19 on MLC. ROCK (Yamashiro *et al.*, 2003), also acts to maintain active myosin by phosphorylating T853 on a subunit of MYPT1, thereby inhibiting the phosphatase activity of MYPT1 by causing dissociation of its catalytic subunit (Kawano *et al.*, 1999; Yokoyama *et al.*, 2005). Collectively, the outcome is assembly and activation of the actin–myosin II contractile ring to mediate membrane ingression. RhoA also interacts with the scaffold proteins anillin and septins, which function to maintain all furrow components within a narrow zone for efficient and complete membrane ingression to ensure a robust cytokinesis.

chromosomes separated during cytokinesis as depolymerization of microtubules results in the newly forming nuclei returning to the center of the cell and fusing (Straight *et al.*, 2003).

Membrane abscission

Membrane abscission also involves two phases: (1) transition from contractile ring closure to formation and maturation of a midbody ring (MR) at the center of the intracellular bridge. This is followed by (2) a secondary ingression or thinning of the intracellular bridge to approximately 100 nm at a site on one side of the MR. This is thought to be the site of abscission, which subsequently follows this secondary ingression

(Figure 6; Elia *et al.*, 2011; Guizetti *et al.*, 2011a; Schiel *et al.*, 2011). In HeLa cells, this process takes approximately 60 mins with daughter cells remaining connected for approximately 40 mins until secondary ingression is initiated and abscission physically separates the two cells (Steigemann and Gerlich, 2009a).

The MR results from compression of the midzone and consists of several proteins (Skop *et al.*, 2004), such as the core structural component γ -tubulin (Julian *et al.*, 1993; Shu *et al.*, 1995), centriolin (Gromley *et al.*, 2003), and the exocyst complex (Gromley *et al.*, 2005). Transition from contractile ring closure (membrane ingression) to MR formation involves anillin (Kechad *et al.*, 2012). Specifically, it is the removal and

Figure 6 Membrane trafficking pathways involved in the abscission phase of cytokinesis. The abscission phase of cytokinesis commences upon formation of the intracellular bridge. In HeLa cells, this phase takes approximately 60 mins to achieve membrane abscission and daughter cell separation. The first approximate 40 mins of the abscission phase is characterized by extensive membrane trafficking events whereby vesicles derived from internal membrane stores including the Golgi, lysosomes, and early and recycling endosomes (Chen *et al.*, 2006; Fielding *et al.*, 2005; Goss and Toomre, 2008; Gromley *et al.*, 2005; Pohl and Jentsch, 2008; Schweitzer and D'Souza-Schorey, 2005; Wilson *et al.*, 2005), are recruited from both daughter cells to the intracellular bridge (Goss and Toomre, 2008). Many proteins involved in vesicle trafficking and membrane fusion locate within the intracellular bridge and specifically dock at the MR, such as Rab11 and SNARE. ALIX and TSG101 (ESCRT-I) accumulate at the midbody and recruit ESCRT-III to the intracellular bridge (Carlton *et al.*, 2008; Elia *et al.*, 2011; Morita *et al.*, 2007). The final approximate 20 mins is marked by constriction of the membrane at a secondary ingression site adjacent to the MR followed by abscission. ESCRT-III components have been associated with recruiting the microtubule severing enzyme spastin, which appears to be required for shearing the microtubules during abscission (Connell *et al.*, 2009; Elia *et al.*, 2011), and this most likely occurs after completion of the secondary ingression but prior to membrane abscission. There are 11 ESCRT-III proteins in mammals and are often called charged MVB proteins (CHMPs). CHMP4B and other ESCRT-III components extend toward the constriction zone while Cep55, TSG101, and ALIX remain confined to the midbody (Guizetti *et al.*, 2011b). ESCRT-III proteins polymerize to form 17 nm filaments within the intracellular bridge that spans a distance of 1 μm from the MR toward the constriction zone. The ESCRT disassembly factor, vacuolar protein sorting-4 (Vps4), is then recruited to the constriction zone and abscission follows immediately (Elia *et al.*, 2011). Membrane abscission is thought to occur due to the inward curving properties of the ESCRT-III filaments or the ability of Vps4 to remodel the cytoskeletal membrane at the constriction site.

retention of anillin at the closing contractile ring and MR, respectively that corresponds with this transition (El *et al.*, 2013). The MR is not contractile and is unable to account for abscission on its own. It appears to act as a scaffold platform for recruiting or activating signaling proteins that contribute to the regulation of abscission and post-mitotic cell fate (Ettinger *et al.*, 2011; Green *et al.*, 2013; Kuo *et al.*, 2011). Proteomics and cell biology studies have indicated that a large number of proteins (>100) locate to the MR itself or to flanking regions within the intracellular bridge (Skop *et al.*, 2004; Steigemann and Gerlich, 2009a). The molecular details of the role of these

proteins, and the interaction between pathways involved in the abscission process, are only starting to emerge. Proteins that accumulate at the MR and flanking regions within the intracellular bridge include those derived from (1) the central spindle such as kinesin-like motor proteins and chromosomal passenger proteins, that travel along the central spindle toward microtubule plus-ends, accumulating in the midzone, (2) the cell equator such as MgcRacGAP, Ect2, and anillin, (3) the equatorial cortex such as RhoA and sept2, and (4) proteins previously located within the nascent daughter cells that traffic to the intracellular bridge upon formation such as

Rab11 and endosomal sorting complexes required for transport (ESCRT)-III. Thus, in human cell lines several lines of evidence suggest that recruitment of key abscission proteins to the midbody are dependent on microtubules and protein trafficking. Indeed, in mammalian cells, vesicles derived from internal membrane stores including the Golgi, lysosomes, and early and recycling endosomes (Chen *et al.*, 2006; Fielding *et al.*, 2005; Goss and Toomre, 2008; Gromley *et al.*, 2005; Pohl and Jentsch, 2008; Schweitzer and D'Souza-Schorey, 2005; Wilson *et al.*, 2005), are recruited from both daughter cells to the intracellular bridge (Goss and Toomre, 2008) and many proteins involved in vesicle trafficking and membrane fusion are required for cytokinesis completion, including the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins, centriolin, exocyst components, dynamin II, and sorting nexin-9 (Chircop *et al.*, 2010; Echard *et al.*, 2004; Gromley *et al.*, 2005; Ma and Chircop, 2012a; Neto *et al.*, 2013a,b; Skop *et al.*, 2004; Smith and Chircop, 2012).

The secondary ingression and abscission process involves depolymerization of cortical actin located within the intracellular bridge (Schiel *et al.*, 2012), which appears to require inactivation of RhoA (Bement *et al.*, 2005; Yuce *et al.*, 2005) as well as depolymerization of microtubules (Elia *et al.*, 2011; Guizetti *et al.*, 2011a; Schiel *et al.*, 2011), trafficking of Rab11-FIP3 recycling endosomes to the MR (Fielding *et al.*, 2005; Schiel *et al.*, 2011, 2012; Wilson *et al.*, 2005), and subsequent recruitment of the ESCRT complexes for abscission (Carlton *et al.*, 2008; Morita *et al.*, 2007). The ESCRT machinery consists of four protein complexes (ESCRT-0, -I, -II, -III) that function in a sequential order and are involved in intraluminal vesicle formation and fission during viral budding and to sort membrane proteins into the endosome lumen to create multivesicular bodies (Raiborg and Stenmark, 2009). In an analogous manner, ESCRT-III proteins polymerize to form 17 nm filaments within the intracellular bridge, spiraling toward the secondary ingression site and driving membrane scission (Figure 6; Guizetti *et al.*, 2011a). After abscission the MR is inherited by one of the daughter cells (Elia *et al.*, 2011; Guizetti *et al.*, 2011a; Pohl and Jentsch, 2009; Schiel *et al.*, 2011).

Although the sequential targeting of the ESCRT machinery is now widely accepted as the final events leading to abscission, the mechanisms regulating this process are still poorly understood. It is proposed that septin filaments drive elongation of the intercellular bridge and generates the secondary ingression site, priming the intracellular bridge for ESCRT-III assembly and abscission (Renshaw *et al.*, 2014). Furthermore, the daughter cells are held together by a high tension pulling force due to cell contractility. This is alleviated when cells stop moving apart and this loss of tension leads to the assembly of the ESCRT-III components at the abscission site, which is shortly followed by abscission itself (Lafaurie-Janvore *et al.*, 2013). Aurora B contributes to regulating abscission timing whereby its activity declines gradually during cytokinesis leading to its inactivation within the intracellular bridge, which subsequently triggers abscission (Steigemann *et al.*, 2009b). Aurora B activity is maintained in cells that contain lagging chromosomes trapped in the intracellular bridge (Mendoza *et al.*, 2009; Steigemann *et al.*, 2009b).

This involves Aurora B-mediated phosphorylation of the ESCRT-III component CHMP4C at S210, which presumably prevents assembly of the abscission complex (Carlton *et al.*, 2012). Thus, Aurora B is a key regulatory kinase that functions to protect the newly formed daughter cells from acquiring DNA damage by preventing premature abscission.

Mitosis As an Anticancer Drug Target

Cancer is characterized by excessive proliferation of cells. This is often due to underlying genetic mutations that result in misregulation of components of the cell division machinery (Chi and Jeang, 2007; Kops *et al.*, 2005; Nicholson and Cimini, 2011; Vogelstein and Kinzler, 2004). Thus causing errors that increase chromosome instability and oncogenic potential, which can subsequently drive tumorigenesis. Therefore it is not surprising that aneuploidy arising from unstable tetraploid cells (Ganem *et al.*, 2007) is a common histopathological hallmark of many cancers, such as the presence of large multinucleated cells observed in glioblastoma multiforme. These tetraploid cells are primarily caused by cell division errors arising from mitotic slippage (premature mitotic exit after prolonged SAC activation), chromosome mis-segregation, and cytokinesis failure.

One of the most successful classes of anticancer chemotherapeutic drugs currently used in the clinic targets mitosis, causing cell death following its disruption (Jackson *et al.*, 2007; Schmidt and Bastians, 2007). These drugs, such as the Vinca alkaloids, target tubulin, by interfering with microtubule dynamics and thus disrupt the mitotic spindle, resulting in prolonged SAC activation that leads to mitotic slippage and cell death. However, microtubules also play important roles in nondividing and noncancer cells. Thus, anti-microtubule drugs have severe side effects in patients such as peripheral neuropathy. Current research is focused on discovering new targets to develop inhibitors of proteins that play critical and exclusive roles in mitosis such as Cdk, Aurora, and Polo kinases as well as kinesin spindle proteins (KSPs) (Jackson *et al.*, 2007; Schmidt and Bastians, 2007). This new targeted class of antimitotic agents are predicted to be as efficacious as anti-microtubule agents, while avoiding many of the adverse side effects. Indeed, many inhibitors of these mitotic proteins have been developed and are currently being tested in clinical trials of various different types of human cancer with promising success (Table 1). Consistent with the mitotic function of these proteins, these inhibitors either inhibit or activate the SAC or cause cytokinesis failure and have been shown to subsequently induce cell death and reduce tumor volume in *in vivo* mouse models of cancer. However, cell death is not always the result as different cancer cell types have varied responses such as senescence and continued cell proliferation. Both of which are undesirable as it would not result in tumor regression but potentially tumor progression. Therefore, a thorough understanding of the molecular mechanisms that control mitotic progression as well as the mechanisms governing cell fate, specifically how cell death pathways are activated, will provide invaluable knowledge to translate new antimitotic compounds into the clinic as improved cancer therapies.

Table 1 Targeted antimetabolic compounds and their effects in cell culture, animal models, and clinical trials

Compound	Cultured cells	Mouse models	Clinical trials	Notes	References
<i>Aurora A inhibitors</i>					
ENMD-2076	Anti-proliferative Myeloma cells	Xenograft tumors H929 tumor Human HT-29 colorectal cancer	Phase I/II Relapsed or refractory leukemia	2010:Orphan drug designation for treatment of acute myeloid leukemia (AML)	Cheung <i>et al.</i> (2011)
MLN8054	Reduced cell viability and promotes apoptosis in p53 deficient cells	Antitumor activity	Phase I Advanced solid tumor, no anti-proliferative affect	Aurora A ATP competitive Affected by Aurora A T217D mutation	Cheung <i>et al.</i> (2011)
MLN8237	Anti-proliferative HCT-116, PC3, SKOV-3, LY-3, MM, and acute lymphoblastic leukemia (ALL)	Xenograft tumors Neuroblastoma and ALL	Phase I/II	Phase I/II	Cheung <i>et al.</i> (2011)
VX-689/MK-5108	Anti-proliferative MCF-7, AU565, SW48, Colo205, SKOV-3, T47D, HCC1419, and BT474 cancer cell lines	Synergistic antitumor activity	Phase I/II CML and ALL	Phase I/II	Cheung <i>et al.</i> (2011)
<i>Pan-Aurora Inhibitors</i>					
AMG-900	Anti-proliferative Effective against MDR1 cells	Xenograft tumors Human HCT-116 tumor and NCI-H460-PTX (MDR over expressing) tumor models	Discontinued	Inhibits auto-phosphorylation of Aurora A and B	Cheung <i>et al.</i> (2011)
AT9283	Anti-proliferative Targets imatinib-resistant BCR-ABL cancer cells		Phase I Refractory solid tumors	Targets Aurora A/B# Orphan drug designation for AML treatment USA and Europe	Cheung <i>et al.</i> (2011)
CYC116	Anti-proliferative	P388/0 murine leukemia mouse model	Phase I Discontinued unknown reason	Aurora A and B	Cheung <i>et al.</i> (2011)
GSK1070916	Anti-proliferative Colo205 cells	Xenograft tumors Lung, colon, and breast cancers	Phase I	Inhibits Aurora B/C-INCENP interaction ATP competitive	Cheung <i>et al.</i> (2011)
PHA-680632	Anti-proliferative	Xenograft tumors HL-60 cells, A2780, HCT-116, and breast cancer models	Phase I Disease stabilization	Targets other kinases	Kitzen <i>et al.</i> (2010)
R763/AS703569	Anti-proliferative A549, DU145, HeLa, Colo205, and U2OS	Xenograft tumors Human pancreatic and leukemia cancers		Targets other kinases	Cheung <i>et al.</i> (2011)
VX680/MK-0457	Anti-proliferative	Xenograft tumors Human AML, colorectal and pancreatic cancer	Phase I/II Suspended		Cheung <i>et al.</i> (2011)
XL228			Phase I	Targets other kinases	Cheung <i>et al.</i> (2011)

Conclusion

Mitosis is a fundamental biological process essential for cellular growth and tissue development. The mechanisms of yeast cell division are well understood. In the last 10 years, a focused effort from many laboratories has begun to expand our understanding of the mechanisms required for animal cell division. In this article, we highlight the morphological events that take place in each sequential stage of mitosis in animal cells and provide an overview of the key signaling proteins/pathways that regulate these events. Specific focus is on cytokinesis, which is the stage of mitosis that researchers have made the most significant advancements in recent years. We also provide some examples of how our understanding of the cell division process is critical to gaining insight into cancer biology mechanisms and how these discoveries may translate into new anticancer therapeutic strategies for better treatment of cancer patients.

Regulating Cytokinesis

G Zachos, University of Crete, Heraklion, Greece

© 2016 Elsevier Inc. All rights reserved.

Cytokinesis, i.e., the process by which the cytoplasm of a cell is separated giving rise to two daughter cells at the end of cell division, is spatially and temporally coupled to chromosome segregation and can be divided into four stages: specification of the cleavage plane, ingression of the cleavage furrow, formation of the midbody and abscission, the final cut of the narrow cytoplasmic canal that connects the two daughter cells (Figure 1; Barr and Gruneberg, 2007; Normand and King, 2010).

In early anaphase, spindle microtubules are of critical importance for selecting the site of cell division (Figure 1). Furthermore, kinase signaling networks, kinesin motors and scaffolding proteins regulate formation of the contractile ring that includes actin and myosin proteins (the actomyosin ring) to promote cleavage furrow ingression. At later stages, membrane fusion events and remodeling of the plasma membrane at the midbody region promote completion of cytokinesis by abscission (Figure 1). Failure of cytokinesis results in formation of tetraploid cells which can lead to carcinogenesis

(Fujiwara *et al.*, 2005). Understanding cytokinesis will therefore give us insight into the process of carcinogenesis and could lead to novel therapeutic strategies to prevent tumor growth by inhibiting cancer cell division. In this article, we discuss recent advances in identifying the mechanisms that regulate cytokinesis in animal somatic cells.

Positioning the Site of Cell Division

The Role of Spindle Microtubules

Central issues in cytokinesis are to ensure that furrowing begins after sister chromatid segregation and the division plane is placed between the two sets of sister chromatids, to make sure that each daughter cell receives a complete set. Temporal regulation of cytokinesis will be discussed later in this article. Correct positioning of the cleavage furrow is controlled by mechanisms that require spindle microtubules (Glotzer, 2004; Burgess and Chang, 2005). There are three models of how microtubules of the early anaphase spindle direct positioning of the cleavage furrow which are not mutually exclusive (Figure 2).

First, equatorial astral microtubules, which extend from the spindle poles across the equator, stimulate formation of the cleavage furrow at the equatorial cortex (Figure 2(a); Canman *et al.*, 2003). Second, polar astral microtubules, which radiate from the centrosomes and anchor the spindle poles to the cell membrane, inhibit cortical contraction by preventing myosin recruitment to the asters to promote contraction at the equatorial region (Figure 2(b); Werner *et al.*, 2007). Finally, central spindle microtubules, i.e., microtubules that partially overlap at the equator with those emanating from the opposing pole, deliver signals that promote positioning of the cleavage furrow at the cell equator (Figure 2(c); Bringmann and Hyman, 2005). It is proposed that these signals provided by different populations of spindle microtubules are partially redundant to ensure efficient formation of the cleavage furrow (Dechant and Glotzer, 2003; Bringmann and Hyman, 2005; Werner *et al.*, 2007).

The RhoA Pathway

What are the positive signals delivered by microtubules that promote positioning of the cleavage furrow at the cell equator? The small GTPase RhoA is the main regulator of actin dynamics in interphase or mitotic cells and several studies suggest that RhoA is a critical target for furrow formation (Piekny *et al.*, 2005). RhoA is activated by the Rho GDP-GTP exchange factor (GEF) ECT2 and inactivated by the GTPase-activating protein (GAP) MgcRacGAP (Piekny *et al.*, 2005). MgcRacGAP forms a complex with the kinesin motor protein Mklp1 (the centralspindlin complex) and is restricted by Mklp1 to the central spindle. Centralspindlin binds ECT2 resulting in accumulation of the active GTP-bound form of RhoA in a

Figure 1 Stages of cytokinesis. Cytokinesis is spatially and temporally coupled to chromosome segregation and can be divided into four stages: specification of the division plane, ingression of the cleavage furrow, formation of the midbody, and abscission.

Figure 2 Spindle microtubules regulate positioning of the cleavage furrow. (a) Equatorial astral microtubules stimulate formation of the cleavage furrow. (b) Polar astral microtubules inhibit cortical contraction at the poles. (c) Central spindle microtubules promote positioning of the cleavage furrow at the cell equator.

narrow zone inside the central spindle (Figure 3; Yuce *et al.*, 2005). It is therefore proposed that microtubules deliver proteins that lead to local RhoA activation. In turn, activated RhoA marks the future cleavage site and organizes furrowing events.

Formation of the Cleavage Furrow

Activated RhoA stimulates actin polymerization and myosin II activity to promote assembly of the actomyosin ring and cleavage furrow ingression. Scaffolding proteins such as anillin and septins are also required for organizing the cleavage furrow and promoting cytokinesis. In addition, the Serine/Threonine kinases Aurora B and polo-like kinase 1 (Plk1) regulate RhoA activity and early furrowing events in animal cells.

RhoA Activity Promotes Actomyosin Ring Assembly

Active RhoA promotes assembly of actin filaments in the contractile ring by binding to formins, a group of proteins involved in actin polymerization (Figure 3; Pollard, 2007). Also, RhoA binds to ROCK and Citron kinases to induce their catalytic activity (Figure 3). ROCK and Citron kinase phosphorylate the myosin light chain (MLC) at positive regulatory

sites and these phosphorylations stimulate localization and motor activity of myosin II at the future cleavage site (Kosako *et al.*, 2000; Yamashiro *et al.*, 2003). Furthermore, ROCK phosphorylates the targeting subunit of myosin phosphatase to inactivate the phosphatase and promote positive MLC phosphorylation (Figure 3; Kawano *et al.*, 1999). As a result, active RhoA directs actin polymerization and myosin II activity at the cell equator. It is proposed that accumulation of actin and myosin II at the cell cortex leads to formation of contractile filaments that are drawn together like a 'purse string' and perform furrow ingression (Wang, 2005).

Scaffolding Proteins: Anillin and Septins

Anillin is a scaffold protein that binds actin filaments, myosin, septins, and activated RhoA (Normand and King, 2010). Anillin localizes to the cleavage furrow at early stages of cytokinesis, directs assembly of septin filaments and contributes to furrow stability during ingression, midbody formation, and abscission (Normand and King, 2010).

Septins are polymerizing GTPases that form filaments and assemble into two rings at the cell cortex on either side of the actomyosin ring (Dobbelaere and Barral, 2004). Septin rings act as barriers to compartmentalize the cortex around the cleavage site and maintain diffusible cortical factors to the site

Figure 3 RhoA activity regulates assembly of the actomyosin ring. RhoA is activated by interaction with the ECT2/RacGAP/Mklp1 complex. Active RhoA stimulates actin polymerization by formin. Furthermore, active RhoA binds to ROCK and Citron kinase to induce activatory phosphorylations of MLC and promote assembly of the actomyosin ring. Also, ROCK inhibits removal of MLC activatory phosphorylations by myosin phosphatase. In addition, Plk1 and Aurora B regulate ECT2/RacGAP/Mklp1 and MLC (see text for details). P, phosphorylation.

of cleavage. In turn, such factors are required for actomyosin ring function and abscission (Dobbelaere and Barral, 2004).

Aurora B and the Chromosomal Passenger Complex

Aurora B kinase is the catalytic subunit of the chromosomal passenger complex (CPC) which also includes regulatory proteins INCENP, Survivin, and Borealin (van der Waal *et al.*, 2012). The CPC associates with chromosome arms in early prophase, localizes to centromeres in prometaphase and metaphase, and then transfers to the central spindle and the midbody in anaphase and telophase respectively (van der Waal *et al.*, 2012). Several studies demonstrate that the CPC is required for central spindle formation, furrow ingression, and late stages of cytokinesis (reviewed in Barr and Gruneberg, 2007). Aurora B phosphorylates Mklp1 and this phosphorylation could be important for central spindle assembly (Figure 3; Kaitna *et al.*, 2000). Also, Aurora B regulates myosin activity by phosphorylating MLC (Figure 3; Murata-Hori *et al.*, 2000). Furthermore, Aurora B phosphorylates MgcRacGAP to activate GAP RhoA activity and this phosphorylation could be important for restricting RhoA activity during furrow ingression or terminating RhoA activity in late cytokinesis

(Figure 3; Minoshima *et al.*, 2003). Also, Aurora B phosphorylates the intermediate filament protein vimentin and is required for filament disassembly during completion of cytokinesis (Goto *et al.*, 2003). In addition, Aurora B is required for the abscission checkpoint as discussed later in this article.

The Role of Plk1

Similar to the CPC, Plk1 also changes localization to various mitotic structures during cell division. Plk1 associates with centrosomes in prophase, is recruited to kinetochores in prometaphase and metaphase, localizes to the central spindle on anaphase and to the midbody in telophase (Petronczki *et al.*, 2008). Acute inactivation of Plk1 at the metaphase-to-anaphase transition prevented ingression of the cleavage furrow and initiation of cytokinesis (Brennan *et al.*, 2007; Burkard *et al.*, 2007). Plk1 phosphorylates MgcRacGAP and this phosphorylation generates a phospho-epitope recognized by ECT2 (Petronczki *et al.*, 2007; Wolfe *et al.*, 2009). Interaction of ECT2 with MgcRacGAP is required for recruitment of ECT2 to the central spindle and subsequent RhoA activation in the cleavage furrow (Figure 3). In addition, Plk1 negatively regulates abscission by phosphorylating Cep-55 (centrosomal protein of 55 kDa) as discussed later in this article.

Formation of the Midbody

After furrowing is completed, the two daughter cells remain connected by a narrow (diameter of 0.1–1 μm) cytoplasmic bridge known as the midbody (Hu *et al.*, 2012). The principal function of the midbody is to localize abscission which physically separates the two daughter cells however, understanding how midbody assembly is regulated is under active investigation. The midbody contains microtubules from the central spindle (also known as the midzone) and includes kinases, actin-binding proteins, microtubule-binding and membrane-associated proteins (Skop *et al.*, 2004). Midbody proteins can fall into three categories depending on their localization (Figure 4; Hu *et al.*, 2012). First, the ‘bulge’ proteins localize to the lump at the center of the midbody and include centralspindlin, ECT2, RhoA, anillin, and Cep-55, a protein required for abscission. Second, the ‘dark zone’ proteins localize to a narrow region on the microtubule bundle in the center of the midbody where tubulin staining is blocked. These include the kinesin protein KIF4, Plk1 kinase and PRC1, a microtubule bundling protein that is essential for central spindle formation. PRC1 is targeted to the central spindle by

KIF4 and in turn recruits the centralspindlin complex and additional mitotic kinesins (Hu *et al.*, 2012). In the absence of PRC1, the cleavage furrow is formed but abscission fails. Furthermore, PRC1 serves as an important docking site for Plk1 in the central spindle, as will be described in a later paragraph (Neef *et al.*, 2007). Third, the ‘flanking zone’ proteins localize to two broad bands of microtubules outside the dark zone and include the kinesin Mklp2 and its cargo Aurora B kinase. Once the midbody is assembled it organizes abscission, the final event of cytokinesis leading to two separate cells.

Abscission

A wide variety of proteins involved in vesicle trafficking and tethering, membrane fusion and plasma membrane remodeling are required for abscission. At this stage, the intercellular bridge has narrowed to approximately 0.2 μm in diameter and human cultured cells may remain connected for several hours before daughter cells are finally separated (Normand and King, 2010).

Vesicle Trafficking

Completion of cytokinesis requires remodeling of the plasma membrane and increased membrane surface at the site of abscission (Figure 5). Membrane trafficking and fusion are essential for those events and both the endoplasmic reticulum (ER)–Golgi and the recycling endosome pathways provide vesicles destined for delivery to the intercellular bridge during abscission (Montagnac *et al.*, 2008; Neto *et al.*, 2011). Noticeably, vesicles accumulate only on one side of the midbody suggesting that delivery is asymmetric (Gromley *et al.*, 2005).

Secretory vesicles derived from the ER–Golgi apparatus are delivered along microtubules down the intercellular bridge in late cytokinesis (Figure 5(a); Gromley *et al.*, 2005). Those vesicles carry vesicle-SNARE (v-SNARE) proteins at their surface which are essential for vesicle tethering and membrane fusion (Gromley *et al.*, 2005). Centriolin, a protein that localizes to the maternal centriole during interphase, is required for tethering vesicles to the midbody (Gromley *et al.*, 2003). Specifically, centriolin recruits components of the exocyst protein complex and, in turn, exocyst proteins tether secretory vesicles to the midbody via interacting with v-SNAREs at their surface (Figure 5(a); Gromley *et al.*, 2005). Furthermore, recruitment of centriolin and exocyst to the midbody is dependent on the Mklp1/MgcRacGAP (centralspindlin) complex (Gromley *et al.*, 2005).

Endocytosis is another source of vesicles for completion of cytokinesis (Figure 5(a); Boucrot and Kirchhausen, 2007). These vesicles are delivered to the midbody through the recycling endosome pathway in the cell body however, endocytosis adjacent to the midbody may also contribute to membrane remodeling during abscission (Figure 5(a), arrowhead). In interphase cells, the small GTPase protein Rab11 localizes to the recycling endosome and is required for the recycling of vesicles to the plasma membrane (Montagnac *et al.*, 2008). During cytokinesis, Rab11-positive vesicles are

Figure 4 Midbody proteins. (a) Depending on their localization, midbody proteins can be classified as ‘bulge,’ ‘dark zone,’ or ‘flanking.’ (b) Midbody localization of the ‘flanking’ protein Aurora B. Confocal microscopy image of a midbody from BE human colon carcinoma cells. Green: Aurora B, red: α -tubulin. Bar, 3 μm .

Figure 5 Late stages of cytokinesis in animal cells. (a) A model for vesicle trafficking and tethering. Secretory (white) or endocytic (gray) vesicles are anchored to the midbody through interactions with exocyst proteins. Endocytosis inside the intercellular bridge is marked by an arrowhead. (b) Membrane fusion. Tethered vesicles fuse with one another or with the plasma membrane through interactions of SNARE proteins. Remodeling of the central spindle causes midbody microtubules to 'bend.' (c) A model for abscission. ESCRT-III proteins form rings around the abscission site and make the plasma membrane curve to separate the daughter cells. Spastin cleaves 'curved' midbody microtubules. (d) After completion of cytokinesis, a midbody remnant is attached to one daughter cell.

transferred along microtubules inside the intercellular bridge by the motor protein kinesin-I (Montagnac *et al.*, 2009). Endocytic vesicles are then recruited to the midbody through

interaction of Rab11-binding proteins, such as FIP3 and FIP4 (not shown), with components of the exocyst complex (Figure 5(a); Fielding *et al.*, 2005).

Membrane Fusion

Following trafficking and anchoring of vesicles to the midbody, SNARE proteins mediate membrane fusion (Montagnac *et al.*, 2008). SNAREs are incorporated into membranes and share a cytosolic segment that is capable of reversibly assembling into bundles of alpha-helices. Vesicle-SNAREs (v-SNAREs) are incorporated in the membranes of transport vesicles whereas target-SNAREs (t-SNAREs) are integrated in target compartments such as the plasma membrane (Montagnac *et al.*, 2008). During abscission, v-SNAREs from recycling or secretory vesicles anchored to the midbody form tight complexes with t-SNAREs (such as syntaxin and endobrevin) into the plasma membrane or other vesicles causing membranes to fuse and generate new sections of the plasma membrane (Figure 5(b); Low *et al.*, 2003; Gromley *et al.*, 2005). Furthermore, accumulation of phosphatidylinositol lipids to endocytic vesicles and the plasma membrane inside the furrow has been proposed to enhance SNARE-dependent fusion and organize abscission (Neto *et al.*, 2011). In addition, vesicle accumulation in late telophase coincides with reorganization of the central spindle and generation of microtubule 'buckles' that may facilitate microtubule severing later in abscission (Figure 5(b); Schiel *et al.*, 2011).

ESCRT Proteins

Recently, endosomal sorting complex required for transport (ESCRT) proteins which are involved in multivesicular body formation and retroviral budding, have been also implicated in abscission (Neto and Gould, 2011). ESCRT subunits form protein complexes (ESCRTs -0, -I, -II, and -III; ALIX; and Vps4) that transiently assemble on specific target membranes and execute membrane scission in a direction away from the cytoplasm, which is topologically opposite to 'classical' vesicular transport involving membrane budding from a donor membrane into the cytoplasm (Henne *et al.*, 2011). In late cytokinesis, Mklp1 kinesin of the centralspindlin complex interacts with Cep-55 which mediates recruitment of ESCRT proteins to the late midbody (Bastos and Barr, 2010). Specifically, Cep-55 interacts with Tsg101 (an ESCRT-I component) and ALIX which in turn recruit ESCRT-III, the complex responsible for scission activity (Figure 5(c); Lee *et al.*, 2008; Neto and Gould, 2011). ESCRT-III proteins assemble in filaments and form rings around the abscission site (Figure 5(c)). These ESCRT-III rings make the plasma membrane curve, eventually driving the final cut that separates the daughter cells (Elia *et al.*, 2011; Guizetti *et al.*, 2011). In addition, ESCRT-III proteins recruit spastin (Yang *et al.*, 2008), a microtubule-severing protein that cleaves 'curved' midbody microtubules to complete cytokinesis (Figure 5(c); Guizetti *et al.*, 2011; Schiel *et al.*, 2011).

The Midbody Remnant

After completion of cytokinesis, a midbody remnant is attached to one daughter cell (Figure 5(d)). This implies asymmetric membrane trafficking and fusion that mediates abscission, however, how this is achieved is not fully understood (Barr and Gruneberg, 2007). The midbody remnant can

be shed to the extracellular space for degradation or internalized into the cytoplasm where it can be degraded by autophagy (Chai *et al.*, 2012).

Temporal Regulation of Cytokinesis

Thus far, we have outlined basic components and mechanisms that control different stages of cytokinesis. These mechanisms have to be temporally regulated to ensure that cytokinesis begins after chromosome segregation. In this section, we will discuss the role of mitotic kinases Cdk1 (Cyclin-dependent kinase 1), Aurora B, and Plk1 in regulating proper timing of cytokinesis.

Cdk1 Inactivation is the Trigger for Initiation of Cytokinesis

Cdk1, in complex with cyclin B (Cdk1/cyclin B), is a negative regulator of cytokinesis and Cdk1/cyclin B catalytic activity must be switched off to allow initiation of cytokinesis (Potapova *et al.*, 2006). In early mitosis, Cdk1/cyclin B activity is high to promote assembly of the mitotic apparatus and chromosome alignment. When all chromosomes become properly attached to spindle microtubules and aligned at the metaphase plate, the anaphase-promoting complex/cyclosome (APC/C) is activated. Activated APC/C is an E3 ubiquitin ligase that targets key proteins, including cyclin B and securin, for degradation, leading to Cdk1 inactivation and sister chromatid segregation (Kops *et al.*, 2005). At the end of mitosis, APC/C also targets cytokinesis proteins, such as Plk1 and Aurora B, for degradation to terminate cytokinesis (Normand and King, 2010).

Active Cdk1 inhibits central spindle formation and furrowing by several mechanisms (Figure 6(a)): First, Cdk1 prevents activation of RhoA by phosphorylating ECT2 at a site that inhibits its association with centralspindlin (Yuce *et al.*, 2005). Also, Cdk1 phosphorylates MLC to inhibit myosin activation (Satterwhite *et al.*, 1992). Furthermore, Cdk1 phosphorylates Mklp1 to reduce its microtubule-binding activity (Mishima *et al.*, 2004). Also, phosphorylation of PRC1 by Cdk1 inhibits its activity to bundle microtubules thus preventing central spindle formation (Jiang *et al.*, 1998). In addition, Cdk1 prevents localization of Aurora B and Plk1 to the central spindle as described in the following paragraphs (Figure 6(b)). After cyclin B degradation (Figure 6(c)), the above inhibitory Cdk1 phosphorylations are lifted to initiate cytokinesis.

Regulation of Aurora B by Cdk1

INCENP and Aurora B mediate recruitment of the CPC to the central spindle after anaphase onset (van der Waal *et al.*, 2012). Cdk1 phosphorylates INCENP and this phosphorylation prevents interaction of both INCENP and Aurora B with Mklp2 and docking of the CPC onto the central spindle (Figure 6(b); Hummer and Mayer, 2009). Because Aurora B is a positive regulator of RhoA, MLC activity and central spindle formation, inhibition of Aurora B localization to the central spindle by active Cdk1 restrains onset of cytokinesis.

Figure 6 Cdk1 kinase activity prevents initiation of cytokinesis. (a) Cdk1 phosphorylates and inhibits ECT2, MLC, Mklp1, and PRC1 in prometaphase and metaphase (see text for details). (b) Cdk1 prevents recruitment of Aurora B and Plk1 to the central spindle. (c) After cyclin B degradation at the start of anaphase, Cdk1 is inactive and cytokinesis begins. (d) Plk1 prevents localization of Cep-55 to the central spindle. (e) At the end of cytokinesis, Plk1 is degraded and Cep-55 accumulates in the midbody to allow recruitment of ESCRTs and abscission. The horizontal dotted line indicates the metaphase to anaphase transition.

Temporal Regulation of Plk1

Plk1 recruitment to different subcellular structures during mitosis progression is mediated by a conserved sequence element at the C-terminus of the protein, termed the Polo-box domain (Petronczki *et al.*, 2008). The Polo-box domain preferentially binds to phosphorylated peptides suggesting that a kinase has to first 'prime' the target site before Plk1 docking

(Petronczki *et al.*, 2008). PRC1 is the major binding partner for Plk1 on anaphase spindles (Neef *et al.*, 2007). In prometaphase and metaphase, Cdk1 primes proteins to target Plk1 to centrosomes or kinetochores. Furthermore, Cdk1 phosphorylates PRC1 at sites that prevent Plk1 binding to PRC1 and docking onto the central spindle (Figure 6(b); Neef *et al.*, 2007). After Cdk1 inactivation at the beginning of anaphase, the inhibitory PRC1 phosphorylations are removed. As a

result, Plk1 phosphorylates PRC1 to self-prime its docking site and associates with PRC1 on central spindle where it plays an essential role in the initiation of cytokinesis (Neef *et al.*, 2007).

Also, Plk1 phosphorylates Cep-55 and this phosphorylation negatively regulates the interaction of Cep-55 with Mklp1 (Figure 6(d); Bastos and Barr, 2010). Only when Plk1 is degraded at the end of mitosis can Cep-55 interact with Mklp1 and accumulate in the midbody to allow recruitment of ESCRT proteins and abscission (Figure 6(e)).

The Abscission Checkpoint Protects against the Deleterious Effects of Chromatin Bridges

Chromatin Bridges

Chromatin bridges are strings of chromatin connecting the two segregating masses of chromosomes in anaphase or daughter nuclei in cytokinesis (Figures 7(a) and 7(b); Gisselsson, 2008). They can be caused by failure to eliminate replication or recombination intermediates during interphase and have been linked to chromosomal instability in human tumors and tumorigenesis in mice (Gisselsson, 2008). Vertebrate cells

recruit DNA helicases, such as the Bloom's syndrome protein helicase (BLM) and the Plk1-interacting checkpoint helicase (PICH), to chromatin bridges to unravel chromatin and promote bridge resolution (Ke *et al.*, 2011; Petsalaki *et al.*, 2014). However, if chromatin bridges are not resolved, attempting cytokinesis in their presence can lead to chromosome breakage and aneuploidy, or cytokinesis can fail and the cell will become tetraploid (Norden *et al.*, 2006; Steigemann *et al.*, 2009; Carlton *et al.*, 2012).

The Abscission Checkpoint

To avoid progression of cytokinesis in the presence of chromatin bridges, eukaryotic cells have evolved mechanisms that delay abscission until the bridges have been resolved, termed 'the abscission checkpoint' (Norden *et al.*, 2006; Steigemann *et al.*, 2009; Carlton *et al.*, 2012). Recent reports show that, in mammalian cells, Aurora B kinase regulates abscission by phosphorylating CHMP4C, a subunit of the ESCRT-III complex that forms rings around the abscission site to execute membrane scission (Capalbo *et al.*, 2012; Carlton *et al.*, 2012). It has been proposed that Aurora B phosphorylation drives localization of CHMP4C from the site of abscission to the

center of the midbody where it can stop abscission (**Figure 7 (c)**; [Carlton *et al.*, 2012](#)). However, exactly how this happens is a matter of active investigation.

Conclusions and Future Perspectives

Cytokinesis is a remarkably complex process that involves multiple components and regulatory pathways. Although many cytokinesis proteins have been identified, the exact mechanism of their function is under active investigation. Failure of cytokinesis can lead to tetraploidy and genomic instability, a prelude of carcinogenesis ([Fujiwara *et al.*, 2005](#)). Furthermore, pharmacologically induced cytokinesis failure in cancer cells may be important as an anticancer strategy and inhibitors of kinases that regulate cytokinesis, such as Plk1 and Aurora B, are being tested as anticancer drugs ([Petronczki *et al.*, 2008](#); [Gascoigne and Taylor, 2009](#)). Because inhibition of the above kinases is likely to induce cytokinesis failure in normal dividing cells in addition to cancer cells, those drugs are expected to induce myelosuppression ([Petronczki *et al.*, 2008](#); [Gascoigne and Taylor, 2009](#)). It therefore remains a challenge to identify conditions under which mitotic inhibitors are able to kill tumor cells while still being tolerated by normal proliferating cells, for example, in the bone marrow.

Regulation of the p53 Pathway

CL Brooks, Stemline Therapeutics, Inc., New York, NY, USA

Introduction

The p53 tumor suppressor gene has been called the ‘guardian of the genome’ and continues to exhibit complex and exquisite regulatory control over cellular functions as a sequence-specific transcription factor (Lane, 1992; Levine, 1997). Great progress has been made since it was first cloned and described in 1979, yet the knowledge gained to date paints an even more complex and intricate role of the gene. Recent findings have shown some surprising and unexpected functions of p53 in normal cells as well, which potentially have broad implications on therapeutics that target this pathway.

As a transcription factor, p53 is highly controlled through a multitude of transcriptional, translational, and posttranslational mechanisms. Normal homeostatic levels of the protein are predominantly regulated through the ubiquitin-proteasome pathway, which maintains p53 at low levels in a cell during normal, unstressed conditions. However, upon sensing of virtually all types of cellular stress, the protein levels of p53 are quickly stabilized and increased, and p53 is activated through numerous posttranslational modifications that can lead to specific outcomes. It has been postulated that the type and magnitude of the stress that a cell experiences guides the type of modifications that occur on p53 and the consequent downstream effect: low to moderate levels of stress can lead to specific acetylation events that drive the expression of genes related to cell growth arrest, thus providing a cell time to repair the damage and survive. However, high levels of stress, which often leads to irreparable damage, is thought to drive acetylation at distinct sites that leads to the expression of genes governing apoptosis and cell death. Nevertheless, this hypothesized model has become more complex with numerous recent findings of p53 involvement in metabolism and normal energy homeostasis.

This article will discuss recent findings into the mechanisms of p53 regulation and activation. It will highlight our current understanding of the p53 pathway and summarize the role of p53 in cellular metabolism. Although there remains much to be learned on this fascinating and complex gene, the package of findings have begun to provide a working model of how p53 governs cellular processes and identifies aspects of the pathway that we may exploit therapeutically. The goal of this section is to provide a larger and more ‘global’ view of the p53 pathway with guidance to recent reviews and work on specific aspects of the biology.

Control of p53 through the Ubiquitin-Proteasome Pathway

Ubiquitination

The cell maintains protein levels and recycles others in part through the efficient and well-controlled ubiquitin-

proteasome pathway. This enzymatically regulated process begins with an E1-activating enzyme, which binds the 76 amino acid ubiquitin and catalyzes acyl adenylation through an ATP-dependent reaction (Pickart, 2001). The ubiquitin moiety is then transferred to an E2-conjugating enzyme through an energy-driven reaction, which subsequently complexes with an E3 ubiquitin ligase. This latter class of proteins provides substrate specificity for proteins targeted for ubiquitination, and numerous E3 ligases have been described for p53 (Lee and Gu, 2010). The most well-known and highly characterized E3 ligase of p53 is mouse double minute 2 (Mdm2) (Hdm2 in humans), which is regulated by p53 through a negative feedback loop. During normal, unstressed conditions, p53 drives the expression of Mdm2; however, during cellular stress signals, the transcription of Mdm2 by p53 is abrogated, leading to an accumulation of the protein that is available for further activation modification. The Mdm2 knockout mouse underscores this intricate feedback relationship between the two proteins, as embryonic lethality is observed at day E6.5, but completely rescued in the double knockout of p53 and Mdm2 (Jones *et al.*, 1995; Montes de Oca Luna *et al.*, 1995; Sharpless, 2005; Sherr, 2001).

Abrogation of the p53–Mdm2 interaction during times of cellular stress can occur through a number of mechanisms, including phosphorylation at Ser15 and Ser20 by Chk1, Chk2, ataxia telangiectasia mutated (ATM), ATR, and DNA-PK (DNA-dependent protein kinase) (Kruse and Gu, 2009). This posttranslational event is thought to physically hinder protein–protein interactions. Acetylation of p53 at the C-terminus of the protein, which is a critical region for transactivation, has also been shown to block ubiquitination at shared lysine residues (Ito *et al.*, 2001; Li *et al.*, 2002a,b). Another mechanism for disruption of the p53–Mdm2 axis involves the tumor suppressor p14ARF, which is a nucleolar protein that binds to and sequesters Mdm2 from p53 in response to oncogenic stress (Sharpless and DePinho, 2004; Sherr, 2001). Moreover, this activity can occur both in and out of the nucleolus (Korgaonkar *et al.*, 2005; Sharpless, 2005). Mdm2 destabilization seems to be an obligatory step for sufficient p53 stabilization and activation (Ohkubo *et al.*, 2006). Cells undergoing a DNA damage response that were treated with proteasome inhibitors to block Mdm2 degradation failed to induce several p53 target genes. Mdm2 destabilization seems to involve DNA damage-induced kinases such as ATM, since treatment with the general kinase inhibitor Wortmannin blocked Mdm2 destabilization in response to stress. More intriguing, however, is the notion that reducing Mdm2 stability is as important as inhibiting its function during a DNA damage response. The half-life of Mdm2 is as short as 5 min during this period, and it is alluring to speculate that phosphorylated Mdm2 may have enhanced self-ubiquitination catalysis. It is possible that the abundance of ubiquitinated Mdm2 during DNA damage is incapable of interacting with p53 due to the sheer speed of degradation, as indicated by its short half-life.

Ubiquitin E3 ligase	Effect on p53
Mdm2	Degradation/nuclear translocation/transcriptional repression
MdmX	Transcriptional inhibition
Ubc13	Degradation
E4F1*	Transcriptional activation
ARF-BP1	Degradation
COP1	Degradation
WWP1	Nuclear translocation

CARP1	Degradation
CARP2	Degradation
TOPORS	Degradation
P300/CBP*	Degradation
MSL2	Nuclear translocation
YY1*	Degradation
Gankyrin*	Degradation

Figure 1 Key ubiquitin E3 ligases of the p53 pathway. Proteins with an asterisk do not function as a classical E3 ligase; rather, these E4 ligases polyubiquitinate a monoubiquitinated substrate.

Additionally, Mdm2 can be degraded within the nucleus under these conditions and this may provide the avenue for quick degradation.

E3 Ligases in the p53 Pathway

A number of other E3 ligases have been described as having specificity for p53, including Ubc13, E4F1, ARF-BP1, COP1, WWP1, and Pirh2 (Lee and Gu, 2010; Figure 1). COP1 and Pirh2 both ubiquitinate p53 independently of Mdm2, and Topors can both ubiquitinate and sumoylate p53 as well (Rajendra *et al.*, 2004; Weger *et al.*, 2005; Dornan *et al.*, 2004; Leng *et al.*, 2003). ARF-BP1 was first identified as a p14ARF binding protein and subsequently shown to directly ubiquitinate p53 as well (Chen *et al.*, 2005; Zhong *et al.*, 2005). Importantly, however, this protein appears to have both p53-dependent and p53-independent activity. In addition, CARP1 and CARP2 ubiquitinate phosphorylated p53 in stressed cells at position S20 (Yang *et al.*, 2007). Taken together, the functions of the various E3 ligases with activity against p53 underscore the critical importance of tight regulation of p53 at all times in a cell and suggest that, although Mdm2 is a critical factor during embryonic development, it is likely not the only factor controlling p53 levels under normal and stressed conditions in mature cells.

Monoubiquitination versus Polyubiquitination

In addition to driving the regulation and degradation of p53 through the 26S proteasome, ubiquitin also has temporal and functional consequences for p53. Monoubiquitination, or the placement of a single ubiquitin or multiple single moieties at distinct lysine residues, has been shown to play an important role in the signaling and localization of several proteins,

including epidermal growth factor (EGF) receptor pathway substrate clone 15 (Eps15) as well as histones H2A and H2B (Ramanathan and Ye, 2012). This process can lead to events such as endocytosis, cell signaling, or transcriptional regulation. As p53 is a nuclear transcription factor, the process of monoubiquitination acts as a unique signal that drives p53 into the cytoplasm through nuclear export for various activities (Li *et al.*, 2003). Mdm2 is capable of inducing both monoubiquitination and polyubiquitination of p53, and monoubiquitination appears to be dependent on Mdm2 levels. Mechanistically, p53-mediated transcription of Mdm2 during times of low or no stress may provide yet another form of regulation for the protein as continuous monoubiquitination of p53 would lead to its translocation into the cytoplasm and away from transcriptional targets in the nucleus. Upon activation of a stress signal, this process would stop and lead to the accumulation of p53 protein levels in the nucleus for further modification and activation. Given the negative feedback loop between the two proteins, high levels of p53 would subsequently drive expression of increased levels of Mdm2, thus leading to the polyubiquitination of p53 and degradation to shut down activity once repairs are completed. Although a simplistic model, this delicate balance of protein levels and precise regulation of p53 activity and location may very well provide the regulatory foundation on which a plethora of other signaling cascades and interacting partners can act.

Cytoplasmic-bound p53 has also been shown to host a range of cellular activities that are independent of transcription. For example, p53 has been shown to bind to apoptotic factors of the Bcl family, including Bcl-2 and Bcl-XL, which mediate the oligomerization of Bak and Bax and play a role in the efflux of apoptotic triggers from mitochondria, including cytochrome *c* (Chipuk *et al.*, 2004; Mihara *et al.*, 2003; Tomita *et al.*, 2006). In addition, p53 has been shown to be further polyubiquitinated in the cytoplasm by p300/CBP thus promoting its degradation (Grossman *et al.*, 2003; Shi *et al.*, 2009). This mechanism of cytoplasmic p300/CBP is distinct from that of protein located in the nucleus, which acetylates p53 for transcriptional activation (see Section Transactivation of p53 through Posttranslational Modifications). Another protein, Synoviolin, is located in the endoplasmic reticulum (ER) and mediates ER-associated degradation (ERAD) of p53 (Yamasaki *et al.*, 2007). Similarly, the anti-apoptotic protein NAPA, which has been shown to promote resistance to the chemotherapeutic cisplatin in cancer cells, can decrease the ubiquitination-mediated degradation of Synoviolin and lead to a decrease in p53 levels (Wu *et al.*, 2011). Although evidence suggests a regulatory involvement of several ER proteins in controlling p53, the specific roles and net outcome of these interactions remain to be elucidated.

Deubiquitination

The ubiquitination pathway is highly dynamic in nature, and mechanisms exist that allow for full reversal of the process. Deubiquitination enzymes (DUBs) have been described in numerous cellular processes, and their role in the p53 pathway has important implications on overall p53 control (Hershko and Ciechanover, 1998; Laney and Hochstrasser, 1999; Pickart

and Eddins, 2004). There are approximately 95 DUBs in the human genome that are divided into five distinct classes: JAB1/MPN/MOV34 (JAMMs), ubiquitin C-terminal proteases (OTUs), Machado-Joseph disease (MJDs), ubiquitin C-terminal hydrolases (UCHs), and ubiquitin-specific proteases (USPs) (Pickart and Eddins, 2004). The first p53-specific DUB identified was Ubiquitin-Specific Protease 7 (USP7), which is also called Herpesvirus-specific Ubiquitin-Specific Protease (HAUSP). USP7 was shown to deubiquitinate and stabilize p53 protein (Li *et al.*, 2002a, 2004). However, soon thereafter it was shown that a USP7 HCT116 knockout cell line exhibited high levels of p53, suggesting a more complex interplay between these two proteins (Cummins *et al.*, 2004). It was subsequently shown that USP7 can also deubiquitinate Mdm2, which exhibits autoubiquitination activity and is a highly unstable protein (Li *et al.*, 2004). Removing USP7 leads to destabilization of Mdm2 and consequently the stabilization of p53, indicating the preferential interaction of USP7 with Mdm2. Tight control of p53 is critical in close proximity to transcriptional targets, yet USP7 has also been shown to localize near mitochondria where it can presumably deubiquitinate monoubiquitinated p53 for further functions required in the cytoplasm. It has also been shown that USP7 can be both ubiquitinated and neddylated, though the consequences of these posttranslational modifications remain unclear (Lee *et al.*, 2005). When N-terminal co-crystal structures were solved for USP7 together with Mdm2, p53, and EBNA peptides, USP7 was shown to have a binding preference for the consensus sequence motif P/AXXS (Sheng *et al.*, 2006). These three proteins all compete for a binding region within a pocket of the N-terminus MATH domain. The mutually exclusive manner of binding, particularly between USP7-p53 and USP7-Mdm2, has important implications in p53 pathway regulation, as discussed below. Interestingly, USP7 has more extensive interactions and forms a more stable complex with Mdm2 even in the presence of excess p53 (Hu *et al.*, 2006).

The p53–Mdm2–HAUSP Connection

The profound effect of DNA damage on Mdm2 temporal stability and the rapid stabilization of p53 suggest an intimate interplay between p53, Mdm2, and HAUSP. Since the half-life of Mdm2 drastically decreases upon stimulation with DNA damage reagents and the binding affinity between HAUSP and Mdm2 goes down upon stimulation with NCS, it is quite likely that HAUSP has a direct role in these observations. Under normal, unstressed, homeostatic cell conditions, HAUSP may preferentially bind to Mdm2 and facilitate its stability at a level sufficient for maintaining p53 at low levels. It has been shown that the binding affinity between Mdm2 and HAUSP is slightly higher ($K_d = 10 \mu\text{M}$) than that between p53 and HAUSP ($K_d = 8 \mu\text{M}$) (Sheng *et al.*, 2006). HAUSP also preferentially binds to Mdm2 *in vitro* when incubated with one molar equivalence of Mdm2 and 10-fold molar equivalence of p53, suggesting a stronger affinity for Mdm2 when the three proteins exist together (Hu *et al.*, 2002). Considering the fact that p53 and Mdm2 share the same binding site within the N-terminal domain of HAUSP, it is unlikely that these three proteins exist as a three-protein complex at the same time.

Rather, the resting state may have a shift in equilibrium in favor of HAUSP–Mdm2 complexes over HAUSP–p53 complexes. This shift would ensure relatively stable Mdm2 that would maintain p53 at low levels when not needed. Upon DNA damage and cellular stresses, however, this shift would be reversed and allow for two mechanisms to take place. First, the binding affinity between HAUSP and Mdm2 would decrease, allowing for free HAUSP molecules to interact with p53 and stabilize the protein by directly removing ubiquitin moieties. Second, the unbound Mdm2 would continue to undergo self-ubiquitination and degradation, shortening its half-life drastically and decreasing the available pool able to ubiquitinate p53. In support of this notion, when HAUSP is removed by somatic knockout in HCT116 cells or transiently reduced in stably transfected HAUSP siRNA cells, the half-life of Mdm2 decreases drastically with a concomitant increase in p53 levels. A similar response also occurs after DNA damage treatment. At an undefined point in the DNA damage response, if DNA repairs were made and signaling pathways allowed for it, the interaction between HAUSP and Mdm2 would be restored and p53 levels would then return to their resting levels.

DUBs in the p53 Pathway

Other DUBs can also affect p53 activity as well as other members of the pathway. USP2a specifically deubiquitinates Mdm2, but not p53, and promotes Mdm2-dependent p53 degradation (Stevenson *et al.*, 2007). Moreover, reduction of USP2a in cells also stabilized p53 and led to its subsequent activation, underscoring the important role of this DUB in regulating Mdm2. USP7 can also deubiquitinate MdmX, which is an Mdm2 homolog that aids the E3 ligase in regulating p53 (Gu *et al.*, 2002; Sharp *et al.*, 1999; Tanimura *et al.*, 1999). MdmX can also promote transcription of p53 by Mdm2, thus leading to the downregulation of the transcription factor (Biderman *et al.*, 2012). USP10 is a cytoplasmic DUB that is activated through ATM phosphorylation after DNA damage occurs, translocates to the nucleus, and deubiquitinates p53 to stabilize and activate the transcription factor (Yuan *et al.*, 2010). More recently, it has been shown that oxidative stress can promote the upregulation of USP29 transcription, which is a DUB that stabilizes p53 (Liu *et al.*, 2011). This activity subsequently leads to p53 activation and the induction of apoptosis. The first OTU family member was recently shown to specifically deubiquitinate p53. The OTU domain-containing ubiquitin aldehyde-binding protein 1 (Otub1) stabilizes and activates p53 to induce p53-dependent apoptosis and cell growth arrest (Sun *et al.*, 2012). However, the activity does not seem to be dependent on its catalytic domain based on mutational analyses. Rather, the protein was shown to bind to an E2-conjugating enzyme specific for Mdm2, UbcH5, thus suppressing Mdm2-mediated ubiquitination of p53 indirectly (Sun *et al.*, 2012). This observation is the first demonstration of a ‘noncanonical’ mechanism of p53 inhibition by a DUB (Sun and Dai, 2014). Taken together, the number of DUBs with specific activity against p53 underscores the importance of this process in balancing p53 protein levels through the ubiquitin-proteasome pathway and reversing the signals marking the protein for degradation.

Transactivation of p53 through Posttranslational Modifications

Acetylation

Acetylation has been well described as a posttranslational event that regulates histones and protein translation with precision, but p53 was the first nonhistone protein shown to be acetylated as well (Gu and Roeder, 1997). The level of p53 acetylation has a direct correlation with protein stabilization and stress-induced activation (Barlev *et al.*, 2001; Ito *et al.*, 2001; Knights *et al.*, 2006; Li *et al.*, 2007; Luo *et al.*, 2004; Rodriguez *et al.*, 2000) and this process stimulates sequence-specific DNA binding (Gu and Roeder, 1997; Liu *et al.*, 1999; Luo *et al.*, 2004; Sakaguchi *et al.*, 1998; Zhao *et al.*, 2006). A number of HATs can acetylate p53 at C-terminal lysine residues (positions 120, 164, 305, 370, 372, 373, 381, and 382), including p300/CREB-binding protein (CBP), HAT p300/CBP-associated factor (PCAF), MYST, hMOF, and TIP60 (Gu and Roeder, 1997; Liu *et al.*, 1999; Sakaguchi *et al.*, 1998; Sykes *et al.*, 2006; Tang *et al.*, 2006; Wang *et al.*, 2003). Acetylation at C-terminal residues also promotes the recruitment and binding of additional transcription cofactors, and it has been shown that some HATs can enhance the acetylation and transcription of proximal target genes (Goodman and Smolik, 2000).

The finding that p53 could be acetylated on a lysine located outside of the C-terminal region (K120) was the first indication that this process may have other consequences than transactivation. The hMOF and TIP60 HATs, which are part of the MYST family, acetylate this unique residue but do not have an effect on DNA binding (Sykes *et al.*, 2006; Tang *et al.*, 2006). Rather, acetylation of K120 was shown to induce the activation of proapoptotic proteins Puma and Bax, which provides a distinct mechanism for inducing apoptosis. The p53-mediated induction of apoptosis through this process occurs after DNA damage signals or p14ARF activation, and preventing acetylation at the site (through introduction of an arginine in place of the lysine) blocked the ability of p53 to induce apoptosis but not cell growth arrest (Tang *et al.*, 2006). These data suggest that acetylation of lysine 120 is crucial for the differential activation of p53 target genes that promote either an apoptosis or cell growth arrest pathway.

Recently, a new acetylation site was described for p53 (Tang *et al.*, 2008). Lysine 164 was identified as a p300/CBP acetylation site by a mass spectrometric analysis of all acetylation sites of p53. Interestingly, mutation of K164 together with seven other C-terminal acetylation sites (creating a p53-8KR expression construct) completely blocked the induction of p21-mediated cell growth arrest. Importantly, single mutations introduced into these sites did not have an overall effect on p53 transactivation activity, suggesting that some compensation can occur by other acetylation sites. However, the combination of all eight sites may be required for specific activation of downstream events. Together, these results underscore the importance of acetylation as an indispensable posttranslational modification for p53 activation.

Deacetylation

Acetylation is a critical process that regulates p53 activity, and as such deacetylation mechanisms exist to tightly control activity.

It has been well established that histone deacetylases (HDACs) can reverse p53 acetylation, including HDAC1 and the class III NAD⁺-dependent SIRT1 (Luo *et al.*, 2001, 2000; Vaziri *et al.*, 2001). Interactions between p53 and these HDACs reduce p53 acetylation levels, leading to termination of p53-dependent transcription of target genes and subsequent cell growth arrest. In addition, the class III NAD⁺-dependent deacetylase SIRT1 was shown to deacetylate p53 (Luo *et al.*, 2001; Vaziri *et al.*, 2001). SIRT1-mediated deacetylation of p53 inactivates the sequence-specific transcriptional activity of the protein and represses p53-mediated cell growth arrest and apoptosis in response to DNA damage and oxidative stress. This process was also shown to prevent p53-dependent transactivation of p21 (Luo *et al.*, 2001). SIRT has been shown to play a role in several other cellular processes in addition to the p53 pathway, which range from metabolism to cellular senescence and aging (Bordone and Guarente, 2005). Although SIRT1 negatively regulates p53 transcriptional activity, the knockout of Sir2a, which is the mouse homolog of SIRT1, shows defects in p53 function in embryonic fibroblasts (Wang *et al.*, 2008). Although p53 is hyperacetylated in these cells, they exhibit defects in DNA repair ability, suggesting that deacetylation and SIRT1 may play additional roles in the p53 pathway. Indeed, SIRT1 is known to be involved in cellular senescence and aging (Bordone and Guarente, 2005). From a survival point of view, these mechanisms may be quite important in response to low levels of cell stress and DNA damage by providing the cell time to make repairs and continue to survive. Thus, deacetylation of p53 by SIRT1 in cells that are experiencing chronic exposure to low levels of damage may push cells into senescence in these mice; these cells have an increased capacity to proliferate in response to chronic, sublethal doses of oxidative stress and fail to mount an adequate DNA damage response (Cheng *et al.*, 2003; Chua *et al.*, 2005). Moreover, SIRT1 has been shown to relocate to sites of DNA double-stranded breaks to help promote DNA repair and can deacetylate the DNA repair protein NBS1 (Yuan *et al.*, 2007). Embryonic fibroblasts from Sirt1-null mice show defects in DNA repair, despite a high steady-state level of acetylated p53. These findings, together with the seemingly opposing results of p53 regulation, suggest that SIRT1 and deacetylation may have an important role in p53-mediated cellular senescence (Tyner *et al.*, 2002; Wang *et al.*, 2008). It is well established that SIRT1 has critical functions in longevity and aging in other organisms such as yeast (Bordone and Guarente, 2005). SIRT1-mediated deacetylation of p53 in response to low levels of DNA damage may therefore promote cellular senescence and help cellular recovery from nonlethal genotoxic events (Wang *et al.*, 2008). However, additional exploration of SIRT1-mediated deacetylation and the net effect on p53 is needed, as the HDAC does not fit the classical definition of a tumor suppressor and mutations in the gene have not been identified to date (Huang *et al.*, 2008; Luo *et al.*, 2001). Nevertheless, current data suggest that SIRT1 may provide a link between the p53 pathway and cellular longevity.

Involvement of p53 in Metabolism

Research of p53 function and regulation has intensely focused on cell growth arrest and apoptosis in response to a multitude

of damaging hits that a cell experiences, which is driven by key p53 responsive genes such as p21, Bax, and Puma. Yet, knockout mice lacking p21 and Puma do not show any increase in the incidence of tumorigenesis, suggesting that p53 may have other functions for maintaining normal cellular homeostasis likely involving metabolic pathways (Choudhury *et al.*, 2007; Michalak *et al.*, 2008; Valente *et al.*, 2013). Through the series of events that occur in dysplastic and neoplastic cells, numerous metabolic pathways are altered that allow a cell to adapt to the increased need for energy and other factors to promote increased proliferation. Indeed, cancer cells are known to have dysregulation of aerobic glycolysis and biosynthesis of macromolecules (Cairns *et al.*, 2011). Notably, p53 has been shown to counteract many of the metabolic changes occurring in tumor cells, such as upregulating mitochondrial OXPHOS and promoting fatty acid oxidation (Maddocks and Vousden, 2011). A recent study of mice carrying arginine mutations in place of lysines at key acetylation sites on p53 (K117, 161, and 162) showed a lack of functions for inducing apoptosis and cell growth arrest, yet still maintained the ability to induce several downstream metabolic targets (Li *et al.*, 2012). This finding indicates that distinct from the well-accepted tumor-suppressive functions through cell growth and apoptosis, p53 has the ability to regulate metabolic pathways as well.

Several metabolic changes occur within a tumor cell that allow it to survive at increased rates of cell proliferation, including an increased glycolytic rate, antioxidant responses, lipid metabolism, and nucleotide biosynthesis (Cairns *et al.*, 2011;

Hsu and Sabatini, 2008). p53 is known to mediate an increase in mitochondrial oxidative phosphorylation by activating Sco2, Gls2, and Parkin (Bensaad *et al.*, 2006; Hu *et al.*, 2010; Kawauchi *et al.*, 2008; Matoba *et al.*, 2006; Schwartzberg-Bar-Yoseph *et al.*, 2004; Suzuki *et al.*, 2010; Zhang *et al.*, 2011). These three genes each play a role in mediating this process: Sco2 increases respiration by regulating cytochrome *c* oxidase within the electron transport chain, Parkin upregulates pyruvate dehydrogenase E1a1 thereby increasing acetyl-CoA levels, and Gls2 can convert glutamine to glutamate as a substrate for glutathione synthesis. More recently, p53 was shown to induce the expression of Tigar, which functions to decrease aerobic glycolysis (Bensaad *et al.*, 2006). Together, these p53-regulated genes promote oxidative phosphorylation and inhibit aerobic glycolysis, which blocks the primary methods of energy utilization in tumor cells. Interestingly, other evidence has shown that Tigar has tumor-protective functions as well by preventing reactive oxygen species (ROS) build up and upregulating nucleotide synthesis (Cheung *et al.*, 2013). In addition, one study found that Tigar promoted the survival of glioma cells under hypoxic and glucose starvation conditions (Wanka *et al.*, 2012). These results raise an interesting paradox, since p53-mediated induction of Tigar may aid tumor cells in adapting to increased metabolic needs and promoting survival. However, the same pathways that promote the survival of tumor cells also aid in protecting normal cells from metabolic stress, and therefore there is likely a fine balance and transitional range when p53 switches from promoting metabolic efficiency to induction of tumor-suppressive functions (Wang and Gu, 2014). This can

Figure 2 Proposed model of p53 regulation. Under normal or low stress conditions, p53 is activated through specific posttranslational modifications that promote the transactivation of metabolic genes and Mdm2, which serves as a regulator in a negative feedback loop. Upon moderate levels of DNA damage that require repair, further modifications of p53, and particularly acetylation at K164 and C-terminal residues, drive the expression of genes that induce cell growth arrest (p21) that allow the cell to repair damage and survive. However, when damage is too extensive for repair, p53 is further posttranslationally modified (K120) to commit the cell to an apoptosis pathway. In cells that have undergone malignant transformation, it is possible that a functional p53 could promote a metabolically favorable environment for the tumor cell to survive.

also be viewed as a 'hierarchy' of response depending on the type and extent of damage a cell is experiencing (Figure 2). When a cell experiences low levels of DNA damage or cellular stress, such as hypoxic conditions, p53 may promote the expression of various metabolic genes as well as Mdm2, which balances active p53 levels below a threshold that would otherwise trigger cell growth arrest or apoptosis. A moderate level of cellular stress, however, may induce acetylation at specific sites of p53 that drive the protein to induce cell growth arrest through p21 induction. Severe and irreparable damage would induce additional acetylation and other posttranslational events that would shift the p53 response down an apoptotic pathway (Wang and Gu, 2014). Further work is needed to understand the precise mechanisms by which p53 regulates metabolic genes and the specific ways in which it transitions from promoting metabolic pathways to inducing tumor-suppressive pathways.

Conclusions

The knowledge base of p53 regulation continues to evolve, and it is becoming evident that this critical tumor suppressor protein has an impact on numerous cellular pathways, including cell growth arrest, apoptosis, and metabolism. *In vivo* studies have indicated that numerous posttranslational modifications are required for p53 to be fully activated, and the precise modifications that occur may dictate the downstream activation of particular pathways. Acetylation is a process that is clearly required for p53 activation, yet we are still elucidating the exact mechanisms by which p53 is activated and how particular acetylation events drive its activity. In addition, the involvement and control of cellular metabolic pathways by p53 has clear implications on normal and tumor cell growth, and therefore a greater understanding of these events and how these processes can be exploited therapeutically is needed. Several human clinical trials of compounds targeting factors of the p53 pathway are currently underway, and therefore future findings will likely provide even greater insight into the impact of this pathway on tumorigenesis.

Cellular Senescence

Introduction

Cellular senescence is a state of permanent cell cycle arrest that was initially defined for cells grown in cell culture. Later on, this cell response was identified both *in vitro* and *in vivo* for cells subjected to different forms of stress, and more recently it has also been involved in physiological situations during development.

The initial observation of cell senescence was done for human primary fibroblasts while trying to establish the optimal conditions of cell culture (Hayflick and Moorhead, 1961). The aim was to have access to a safe source of human unperturbed cells that could be used for vaccine development and other biotechnological applications. At that time, early cell culture technology relied on the use of established cell lines derived from human and mouse tumors. In contrast to the robust and permanent proliferation observed for the tumor cells, human primary fibroblasts could be adapted to *in vitro* conditions of cell culture and proliferated at a constant rate during the initial phases of the culture. However, invariably as cultures accumulated passages, cells changed to a flattened and enlarged morphology and ceased to proliferate. This growth arrest was stable since addition of new growth factors did not result in resumed cell division.

These observations led the authors to relate cell senescence with the process of aging. Proliferative exhaustion was seen as the cellular reflection of organismal decay. In contrast, tumor cells were immortal and did not show any signs of cell senescence. One key element derived from this theoretical framework is that cells need to have a counting mechanism responsible for triggering the senescence program. This prompted many laboratories to initiate the search for factors that could be involved in regulating the entry into senescence as a way to decipher the molecular mechanisms underlying aging.

Decades later, while trying to model cancer initiation after oncogene activation, cell senescence was identified as a response opposing oncogenic transformation (Serrano *et al.*, 1997). Cells carrying an activated oncogene were shown to either die through apoptosis or enter the characteristic stable cell cycle arrest that defines cell senescence. These observations were substantiated *in vivo* using animal models and human samples undergoing oncogenic stress, and cell senescence proved to be a powerful barrier blocking tumor development (Collado and Serrano, 2010).

Oncogenic activation was the first example of cell senescence induction as a response against a stress that could potentially alter the cellular integrity. Other stresses soon followed and cell senescence started to be seen as a common protective response preventing proliferation of damaged cells (Shay and Roninson, 2004).

Recently, the identification of cell senescence during embryonic development as a remodeling mechanism opens up

the possibility that senescence originated as a physiological process that was co-opted in adulthood to respond in stressful conditions (Campisi, 2014). The implications of cell senescence for the normal physiology of tissues in healthy conditions, or during aging or disease are still a matter of intense investigation, but the relevance of this cellular response is undisputed.

What Defines Cellular Senescence?

No definitive marker of cell senescence exists and cumulative evidence is required to define a cell as senescent. From the initial identification of cell senescence, the main feature of this process is the stable cell cycle arrest. Even though cells remain metabolically active, they can no longer re-enter the cell cycle. This growth arrest is imposed by cell cycle regulators such as the cyclin-dependent kinase inhibitors of the INK (p15, p16, p18, and p19) and CIP/KIP (p21, p27, and p57) families. Identification of high levels of these proteins together with the concomitant absence of proliferation markers, are indicative of a possible cell senescence response. However, quiescence or transitory growth arrest can also result in increased levels of cell cycle inhibitors and lack of proliferative markers. *In vitro*, cells adopt a typical appearance characterized by enlarged and flatten morphology although the relevance of this change in morphology has never been proved *in vivo*.

The most widely used marker of cell senescence is the enzymatic determination of lysosomal beta-galactosidase (Dimiri *et al.*, 1995) known as SA-beta-gal (for senescence-associated beta-galactosidase) activity. For not totally understood reasons, the lysosomal content of senescent cells increase. In parallel, mRNA transcription and protein synthesis from the GLB1 gene also increase. Lysosomal beta-galactosidase activity is usually assessed through a chromogenic reaction employing a galactose analog, X-gal. The reaction is optimal at pH 4.0–4.5 but when performed at a suboptimal pH of 6.0, only cells with increased lysosomal content and high beta-galactosidase activity, that is, senescent cells, are detected (Kurz *et al.*, 2000). This situation provides a useful, although limited marker to detect senescent cells. The beta-galactosidase activity is not functionally related with the senescent process, since experimentally decreased expression or absence in patients with autosomal recessive G(M1)-gangliosidosis, carrying a defective lysosomal beta-galactosidase enzyme, do not show any defect in senescence induction (Lee *et al.*, 2006). Besides, some reports showed positive artefactual reactions not linked to senescence.

Numerous gene expression changes have been proposed to underlie cell senescence, although the generality and relevance of each individual change is difficult to define. Particular molecular signaling pathways, epigenetic changes, and secreted factors have been identified and might play important

roles during senescence, but these features could be only taking place in particular situations and will be discussed later.

Molecular Signaling Pathways

The description of cell senescence after proliferative exhaustion in culture implied the existence of a molecular mechanism capable of counting cell divisions, or more generally speaking, a mechanism that could sense the proliferative history of the cell. At the end of the last century, with the detailed study of the structure and function of telomeres, nucleoprotein structures protecting the tip of the chromosomes, they became an obvious candidate to be playing this role in the cell. Cell division leads to the shortening of the repetitive DNA at telomeres due to the end-replication problem, the impossibility of the DNA replication machinery to completely copy both strands of DNA. The accumulation of cell divisions thus results in attrition of telomeres up to a point in which they lose their protective capacity and the extremes of chromosomes end up being recognized as sites of DNA damage by the repair machinery (Harley *et al.*, 1990). This damage triggers a tumor suppressive response with cell senescence as one of the possible outcomes, being apoptosis another potential consequence of DNA damage at telomeres. The nature of the cellular decision remains elusive.

Another consequence of consecutive cell divisions is the accumulation of unresolved genomic damage at sites different from telomeric regions. The inevitable consequence of errors derived from an imperfect DNA replication process, or not completely repaired DNA damage, is a genome that piles up increasing levels of lesions. This situation cannot be tolerated by the cell, due to the risk that injured genomic information would pose for the integrity of the message that has to be passed from cell to cell. Unrepaired DNA damage results in the activation of p53 tumor suppressor and, again, in the induction of senescence or apoptosis (d'Adda di Fagagna, 2008).

Finally, another important player in determining the entry into the senescent growth arrest after serial passage is the derepression of the *Ink4a/ARF* locus (Gil and Peters, 2006). This locus is a remarkable genomic region that encodes for two structurally unrelated tumor suppressors, p16 and ARF (p14 in humans and p19 in mice). This locus stays silent in primary cells and becomes activated only after cumulative cell divisions (Figure 1).

Interestingly, other triggers of cell senescence result also in the activation of these molecular pathways (Collado *et al.*, 2007). Aged tissues show telomere shortening and DNA damage signaling that emanates from dysfunctional telomeres. Oncogene induction activates p53 and the *Ink4a/ARF* locus, and can cause replicative stress that signals through the DNA damage response pathway.

Epigenetic Control of Senescence

The irreversibility of the growth arrest imposed by cell senescence has an epigenetic basis. De novo heterochromatin formation of genomic regions carrying genes with crucial roles promoting cell proliferation is a hallmark of senescence. These regions are known as senescence-associated heterochromatin

Figure 1 Molecular pathways leading to cell senescence. Different stress signals might engage the cell senescence machinery. The main inducers of cell senescence are telomere shortening, unresolved DNA damage accumulation, and oncogene activation. These different stressors converge on common cellular pathways governed by the *Ink4a/ARF* and p53 tumor suppressor genes. The activation of these molecules imposes a stable cell cycle arrest, although other alternative end points, such as reversible growth arrest (quiescence) or cell death (apoptosis), are also possible.

foci (SAHFs) (Narita *et al.*, 2003) and can be visualized through different methodological approaches. Compacted chromatin, visualized as intense 4',6-diamidino-2-phenylindole (DAPI)-stained DNA or the presence of Lysine 9 trimethylated histone H3 and HP1 γ , are features of the heterochromatin nature of these genomic areas. SAHFs are also

characterized by their accumulation of HMGA proteins (non-histone chromatin architectural proteins) and depletion of linker Histone H1 (Narita *et al.*, 2006; Funayama *et al.*, 2006). Efforts to decipher the sequence of events that culminate with the establishment of this epigenetic regulation and the molecular players involved has provided us with a better understanding of this strict control (Chan *et al.*, 2005; Zhang *et al.*, 2005; Funayama *et al.*, 2006; Narita *et al.*, 2006; Ye *et al.*, 2007). However, there is no proof for a direct causal relationship between SAHF formation and the particular regulation of specific genes involved in senescence.

Secreted Factors

Since senescent cells are characterized by their stable exit from the cell cycle, it was assumed that this response was an end point that enabled efficient management of stress responses. However, senescent cells remain metabolically active once they stop dividing and in recent years it has become clear that they specifically produce a high number of secreted factors. Senescent cells release a plethora of factors mainly extracellular proteases, cytokines and chemokines, and perhaps counter intuitively growth factors (Coppé *et al.*, 2010). These secreted factors are known collectively as senescence-associated secretory phenotype (SASP). The SASP has a wide range of potential activities, with both autocrine and paracrine effects proposed, and with both beneficial and detrimental activities. In the initial description of the SASP, secreted factors were identified as reinforcing the senescence cell cycle arrest in an autocrine manner (Kuilman *et al.*, 2008; Acosta *et al.*, 2008). From this point of view, the SASP would act in an autocrine manner and be beneficial. Some reports also suggested that senescent cells use the SASP as a chemical message to alert neighboring cells and extend the senescence phenotype (Acosta *et al.*, 2013) acting in a paracrine manner to prepare the tissue to confront a potential damage. Even though *in vitro* senescent cells have always been considered to remain alive for prolonged periods of time, the situation *in vivo* might be different and the SASP has also been pointed as responsible for attracting immune cells to the sites of damage to clear up damaged growth-arrested cells (Hoenicke and Zender, 2012). Strikingly, some of the secreted factors have obvious links with pro-inflammatory signals that have been traditionally considered to exert pro-tumoral actions. These led many investigators to propose that a potential detrimental action of senescent cells accumulating at sites of damage or during aging could be the result of a constant low level inflammatory reaction. Some authors have proposed that in the context of oncogene activation cell senescence exerts an antitumor action with a SASP that can switch from cancer-inhibitory to cancer-promoting depending on the integrity of tumor suppressor p53 (Pribluda *et al.*, 2013). This pro-inflammatory signals derived from senescent cells have also been proposed to be responsible for promoting proliferation of premalignant or fully tumorigenic neighboring cells (Davalos *et al.*, 2010; Coppé *et al.*, 2010). Some authors even proposed that the SASP could be responsible for promoting a more malignant and metastatic phenotype in cancer cells (Yu *et al.*, 2013; Angelini *et al.*, 2013), something that would imply that potential therapies aimed at

inducing cancer cell senescence could be even dangerous (Figure 2).

Senescence in Aging

Originally, the finite proliferative capacity of cells was seen as a reflection of the process of aging. Understanding the molecular mechanisms that control this process was considered a way to reveal the limit of the life span of an organism and the key to reverse aging. In human cells, telomere shortening was identified as responsible for triggering senescence after prolonged culture (Harley *et al.*, 1990) and the regulation of telomeres has become a crucial field in aging biology. Different studies showed accumulation of SA-beta-gal-positive cells in aged tissues as well as an age-dependent increase in the expression of senescence markers (Herbig *et al.*, 2006; Wang *et al.*, 2009). Signs of DNA damage at telomeric regions increase with age and this has been seen as an *in vivo* proof of the *in vitro* observations. All these 'signs' of senescence are more prominent in tissues from animal models and human patients suffering premature aging syndromes (Gonzalo, 2014). However, a causative relationship between senescence and aging is not completely clear. A correlation between donor age and *in vitro* proliferative potential is controversial (Cristofalo *et al.*, 2004). At the same time, cells derived from premature aging syndrome patients become senescent more readily in culture compared with young or healthy individuals (McClintock *et al.*, 2006).

Some authors proposed that the age-dependent accumulation of senescent cells occurs in stem cells and progenitor compartments in various tissues, limiting the regenerative capacity of those organs during aging (Sharpless and DePinho, 2007). However, there is no formal proof that these cells were actually undergoing senescence since this description relied only on the identification of increased p16 in these cells (Molofsky *et al.*, 2006; Krishnamurthy *et al.*, 2006; Janzen *et al.*, 2006). Using mouse models of premature aging, other authors proposed a role for an exacerbated cell senescence response in the premature aging phenotype (Baker *et al.*, 2006). Deletion of p16 was shown to improve some of the aging phenotypes but again, it is not clear that this was causing a decrease in senescence (Baker *et al.*, 2008). Recently, selective killing of p16-positive cells in this same premature aging mouse model ameliorated the aging phenotype, but had no effect on global life span (Baker *et al.*, 2011). To add more confusion, mice carrying extra gene dosages of the whole Ink4a/ARF locus (coding for p15, p16, and p19ARF) actually showed prolonged life span (Matheu *et al.*, 2009), similarly to what was also shown for animals with reinforced p53 and Ink4a/ARF (Matheu *et al.*, 2007).

Senescence in Cancer

Senescence of human diploid fibroblasts after long-term cell culture *in vitro* was received with incredulity due to the experience with human tumor derived cell cultures that can be maintained essentially indefinitely. This different behavior implies that tumor cells evade this response as part of the essential changes that make them tumorigenic (Hanahan and Weinberg, 2000). Investigation of the molecular players

Figure 2 Role of senescence-associated secretory phenotype (SASP) in cancer and aging. The SASP can have both beneficial and detrimental effects on senescent cells and surrounding tissue. In cancer, after cell senescence triggered by oncogenic stress, cells secrete various SASP components that might result in enhanced cell senescence or escape from the growth arrest depending on other not well-defined circumstances. During aging, there is a shift from a beneficial contribution of the SASP to tissue homeostasis after cell senescence induced by sporadic damage, to a detrimental action exerted in old tissue due to accumulated damage that is not effectively resolved by immune clearance. Excessive SASP in aged tissue might contribute to age-related diseases.

involved in senescence showed that the cell cycle arrest was mediated by the main tumor suppressor networks of the cell, ARF/p53 and INK4a/RB (Hara *et al.*, 1991; Shay *et al.*, 1991; Bond *et al.*, 1994; Lin *et al.*, 1998; Schmitt *et al.*, 2002; Beauséjour *et al.*, 2003; Collins and Sedivy, 2003; Oren, 2003; Herbig *et al.*, 2004; Jacobs and de Lange, 2004; Ohtani *et al.*, 2004; Chen *et al.*, 2005; Campisi and d'Adda di Fagagna, 2007; Rodier *et al.*, 2007). Loss of these tumor suppressors is an essential requisite to render cells insensitive to the senescent arrest, that is, to become immortal (Hahn *et al.*, 2002; Hahn and Weinberg, 2002), and an extremely frequent event in human cancer (Hollstein *et al.*, 1991; Ruas and Peters, 1998; Sharpless and DePinho, 1999). Thus, cell senescence could be considered as a tumor suppressor mechanism. This idea was experimentally exposed when an activated oncogene was introduced into normal human diploid fibroblasts (Serrano *et al.*, 1997). Expression of the oncogene triggered an immediate phenotypic change that was identical to the one observed after serial passage, and the permanent cell cycle arrest, mediated by p16 and p53, was considered an efficient tumor suppressive barrier. *In vivo* evidence for the existence and

relevance of this oncogene-induced senescence was provided later on using animal models of oncogenic activation and human samples derived from cancer patients. Premalignant tumors arising from experimental oncogenic activation in genetically modified animals (Braig *et al.*, 2005; Chen *et al.*, 2005; Collado *et al.*, 2005) or samples obtained from cancer patients (Michaloglou *et al.*, 2005) were shown to be restricted by senescence induction. Avoiding the senescence response by deletion of the main tumor suppressor genes is fundamental for tumor progression and this correlates with the absence of the senescence response *in vivo* (Chen *et al.*, 2005). The growing list of studies showing similar results (Collado and Serrano, 2010) clearly argue for cell senescence as a basic mechanism restraining cancer through a cell-autonomous block of the proliferation of oncogenically primed cells.

Despite the universal requirement for a tumor cell to bypass the senescence growth arrest, some chemotherapy treatments have the ability to cause senescence of cultured tumor cells (Shay and Roninson, 2004), and *in vivo* grown tumors (Schmitt *et al.*, 2002; Coppé *et al.*, 2008). To which extend this is also occurring in human tumors after standard chemotherapy is

currently unknown, with only limited evidence described for some tumors (Poele *et al.*, 2002; Roberson *et al.*, 2005; Haugstetter *et al.*, 2010), but it would be very important to clearly establish the potential contribution of therapy-induced senescence. Interestingly, experimental reactivation of tumor suppressor p53 in tumors generated in its absence has the potential to control tumor growth either by inducing apoptosis or senescence depending on the tissue (Ventura *et al.*, 2007; Xue *et al.*, 2007). Furthermore, the induction of senescence is rapidly triggered even after short transient re-expression of p53 and is associated with tumor regression. This tumor regression after senescence induction is achieved through the action of the immune system. Again, the SASP seems an obvious candidate to be mediating such a process.

Given the theoretical irreversibility of cell senescence and the requisite to escape from this control for a tumor to grow, it is not clear how tumor cells manage to avoid the action of senescence. Either tumor cells acquire senescence deactivating mutations early on in their path toward full neoplastic transformation, or they suffer mutations, epigenetic alterations, or activate signaling pathways that can reverse the senescent growth arrest. One possible source of signals that could promote escape from senescence comes from the immune system. Pro-tumorigenic inflammation has been shown to cooperate with oncogene activation to dismantle the defense response of the cell in animal models of oncogenic induction in the pancreas (Guerra *et al.*, 2011) or colorectal epithelium (Pribluda *et al.*, 2013). Interestingly, recent data show that Gr1 + myeloid cells (a particular immune cell type) are attracted to the tumors by signals released by transformed cells. These myeloid cells are recruited to the tumors to take advantage of their senescence antagonizing activity (Di Mitri *et al.*, 2014).

Senescence and Tissue Repair

As already discussed, senescent cells are characterized by the release of multiple factors to the extracellular microenvironment, the SASP. Among them, several molecules have a clear involvement in tissue repair. Several growth factors and proteases that participate in wound healing, chemoattractants for immune cells, and proteins that mobilize stem or progenitor cells are in the lists of SASP components. Thus, senescent cells communicate with the surrounding tissue through the SASP to alert neighboring cells and the immune system about cellular damage and to stimulate repair. This function has been exemplified in recent work that revealed the role of senescence during tissue damage repair in liver. Acute liver damage activates stellate cells that, as a result, proliferate and secrete extracellular matrix (ECM) components that produce a fibrotic scar. After this initial reaction, stellate cells undergo senescence, stop producing ECM and in turn secrete SASP components that degrade the ECM, limiting excessive liver damage. When the senescence response is compromised by the lack of crucial senescence mediators such as p53 or *Ink4a/ARF*, the fibrotic reaction is disproportionate resulting in detrimental severe fibrosis that limits tissue repair (Krizhanovsky *et al.*, 2008). In another study, CCN1 was identified as a senescence mediator increased in human cirrhotic liver and in acutely damaged liver in mice. When CCN1 was deleted in genetically modified mice, the senescence process was impaired

and the fibrotic response was concomitantly exacerbated after liver damage (Kim *et al.*, 2013). Finally, another factor, IL22, was also shown to be hepatoprotective due to its ability to contribute to senescence induction of stellate cells, ameliorating excessive liver fibrogenesis (Kong *et al.*, 2012).

Similarly, skin damage leads to the induction of cell senescence of myofibroblasts during wound healing, restricting the fibrotic response, a process in which CCN1 has also been shown to play a similar role than the one played in liver. Interestingly, topical application of CCN1 protein to wounds induces senescence of fibroblasts and this response functions to curb fibrosis during skin repair (Jun and Lau, 2010).

In summary, mounting evidence point to a positive role for the senescence response as a process involved in normal tissue repair. In this context, the SASP seems to operate as a beneficial mechanism to favor tissue remodeling and regeneration.

Senescence in Development

Senescence gained a reputation as a stress response after its identification in cell culture and through its involvement as an anticancer barrier. Many saw the senescent growth arrest as a mechanism that evolved to secure the integrity of the genome and its putative role in aging as an undesired unselected detrimental side effect. With mounting evidence of senescence being involved also in beneficial responses related with tissue repair and remodeling, the question of a possible role for senescence in physiological embryo development was recently addressed by two groups. The identification of SA-beta-gal-positive cells in the transitory kidney, the endolymphatic sac of the inner ear, the closing neural tube and the apical ectodermal ridge, among other structures in the embryo, proved that cell senescence operates during embryogenesis (Muñoz-Espín *et al.*, 2013; Storer *et al.*, 2013). All these structures seem to trigger senescence through the action of the cell cycle inhibitor p21, and not through the common senescence regulator p16, and surprisingly, in a p53 independent manner. Senescent cells in the embryo seem to be cleared by the action of the immune system, very much like what has been described for adult tissues undergoing a stress response. Also, at least for some of these structures, released factors seem to play a crucial role promoting cell growth and ECM remodeling to allow tissue development, resembling the role of cell senescence in tissue repair. All these similarities raise the question of a possible evolutionary origin of cell senescence operating during embryo development and being co-opted during adulthood for its positive activities.

Conclusion

Once considered the basis of the process of aging, the causative relationship of cell senescence in aging still remains a matter of debate nowadays. The description of oncogene-induced senescence offered a plausible mechanism of tumor suppression based on the implementation of a permanent cell cycle arrest, and marked the way for a new view of senescence as a stress response. This positive effect protecting us from cancer was mirrored by the putative detrimental action that the accumulation of senescent cells could have with aging. This was seen by

many as an example of the antagonistic pleiotropy hypothesis of evolution. According to this idea, cell senescence could have been selected during evolution to serve a positive function stopping damaged cells from dividing and forming a tumor. Later in life, senescence would show its negative face, once the reproductive age was passed, and accumulation of senescent cells would interfere with the proper activity of the tissue. However, giving its function avoiding the emergence of damaged cells, and as promoter of repair and remodeling to help maintain tissue homeostasis, the accumulation of senescent cells with age could have new interpretations. The high numbers of senescent cells during aging could turn out to be considered the reflection of a futile effort to restore normal tissue function. The recent identification of cell senescence during embryonic development opens

yet a new avenue of research and defects in this process could have unexplored pathological consequences in adulthood. To which extent cell senescence has similar positive functions in normal unstressed conditions is something that remains to be addressed. Further studies into this exciting field would provide us with a better understanding of basic cell biology mechanisms and opportunities for more effective therapies (Figure 3).

Figure 3 Programmed and stress-induced senescence. Recent work has identified programmed cell senescence as part of the developmental program, helping shape different tissues, and structures during embryogenesis. This discovery opens new possibilities regarding the pathological consequences that might derive from a defective or excessive cell senescence response during development. In the adult, stress-induced cell senescence has been shown to provide a barrier against tumor development and to contribute to tissue repair. The absence of an effective cell senescence process can result in tumor progression or an excessive fibrotic response. Similarly, an exacerbated or prolonged cell senescence response might promote tumor cell growth or result in dysfunctional aged tissues.

Glossary

Antibody The secreted splice variant of the antigen-binding effector molecule generated by B lymphocytes. It is the product of three somatic gene modifications: recombination of variable, diversity and joining gene segments, somatic hypermutation and class switch recombination. Antibodies are secreted in large amounts by plasma cells.

B cell receptor The cell surface splice variant of the antigen-binding receptor on B cells that is generated through three somatic gene modifications: recombination of variable, diversity and joining gene segments, somatic hypermutation and class switch recombination. Alternatively spliced forms are expressed on the cell surface where they serve primary roles of signaling and antigen capture or secreted forms that are involved in immune effector function. Also referred to as immunoglobulin or antibody.

Caspase A family of proteases that are involved in control of cell death pathways.

Cluster of differentiation The common nomenclature system that is used to disambiguate surface molecules in the human and mouse based on monoclonal antibody staining patterns across stages of leukocyte differentiation.

Immunoglobulin superfamily A large family of proteins that share a common globular domain of ~100 amino acids with two β sheets of 3–5 strands often joined by an intrachain disulfide bond. The level of homology can be low ($\geq 20\%$) such that criteria for inclusion are typically based on a number of criteria including structural prediction, intron-exon boundaries, and, most definitively, X-ray crystallographic structures.

Immunological synapse A cell–cell junction stabilized by adhesion molecules and directed by innate or adaptive immune recognition with effector functions carried out by polarized secretion or extracellular vesicle budding.

Inflammasome A cytoplasmic complex that mediates induced innate immune reactions associated with injury or infection.

Integrin A family large heterodimeric adhesion molecules that display activation regulated, divalent cation dependent binding of ligands and create an integral membrane bridge to the cytoskeleton.

Interleukin Small proteins that mediate communication between cells in the immune system. There are currently 36 interleukins with the designation IL-1 through IL-36.

Isotype class The variable domain of an antibody can be linked to different effector domains through ‘class switching,’ which is regulated by activation induced cytosine deaminase (AID) and transcription from promoters of gene segments encoding different ‘constant’ domains.

Peripheral node addressin A sulphated sialyl lewis X carbohydrate antigen associated with sialyl mucins such as CD34 expressed on high endothelial venules of lymph nodes. It's the ligand for CD62L on leukocytes.

T cell receptor The antigen-binding receptor on T cells.

Toll-like receptor A family of type I transmembrane proteins with leucine rich repeats in the extracellular domain and cytoplasmic domains that link to signal transduction to stimulated induced innate immunity. The ligands include conserved macromolecules from pathogens and some endogenous molecules released or generated in conditions of tissue injury.

Variable lymphocyte receptor Leucine rich repeat type receptors that are generated by somatic gene rearrangements in jawless fish that are responsible for adaptive immunity. An alternative structural scaffold to the immunoglobulin superfamily for generation of combinatorial diversity to recognize diverse pathogens.

Virulence factor Gene products that code for proteins that enhance the fitness of a pathogen to survive in the host and spread to new hosts.

Introduction

One of the fundamental concepts in cell biology is that cells build barriers to create compartmentalization of life processes and infection takes place when these barriers are compromised by another organism at the expense of the host. The

compartments can be within the cell itself or formed by co-operation of many cells in a multicellular organism. We will define immunity as mechanisms that reinforce these standing barriers to protect host compartments and the response of the host once these barriers are breached or functionally compromised. These same mechanisms may also manage

colonization with helpful microbes to achieve optimal fitness in the community. All self-replicating organisms engage in activities that could be considered a form of immunity to infection. Human infectious agents are subdivided into three major groups (1) viruses and intracellular bacteria, (2) extracellular bacteria and fungi, and (3) protozoan and multicellular parasites. These divisions are not taxonomic, but are based on studying how the host organizes its immune response to these categories of invaders. All self-replicating organisms need to cope with infection – including bacteria, plants, protists, and invertebrate animals. This section on the functional cell biology will focus attention on human immunity and model organisms that are studied to better understand principles of human immunity to infection. Model organisms are quite diverse and include flies, jawless and jawed fish, and other mammals. We will further focus on how functional immunity relates to cell biology principles learned from studying model cells and developmental processes.

We can divide the immune response into interconnected innate and adaptive branches. Innate immunity refers to evolved strategies to prevent barrier compromise and mount a rapid response to infection once a barrier breach occurs. In the first stage of an innate immune response, the body detects the presence of a threat, which is typically the presence of a molecule derived from an infectious agent. This ability to discriminate an entity as foreign or out of place, referred to as ‘self versus nonself,’ is essential for both innate and adaptive immunity. Innate immunity takes advantage of evolutionarily conserved characteristics of pathogens, which includes the ability to survive in particular physical environments and conserved molecular signatures of the pathogen that are not found in the host, such as components of the bacterial cell wall. The innate immune system can also be triggered by the presence of a host-derived molecule that is foreign to a particular compartment, such as genomic DNA that is present outside of the nucleus or cell. The mislocalization of host molecules is often a consequence of an injury that coincides with infection. These molecules that are foreign or perceived as danger signals can be recognized by germline-encoded receptor systems to initiate inflammation. Inflammation is a coordinated local and systemic response that rapidly acts to prevent the spread of the pathogen and create conditions that will destroy most invading organisms. All multicellular organisms have elaborate innate immune mechanisms that lead to inflammatory response; even bacteria have counter-measures to control propagation of phages (viruses that infect bacteria) such as the Crispr-Cas system, which also has practical utility in genetic engineering. Vertebrates, including jawed fish, reptiles, amphibians, birds, and mammals, have an additional layer of adaptive immunity which is defined by the ability to select new receptors to recognize nonconserved macromolecules of pathogens that more efficiently focus inflammatory mechanisms to eradicate pathogens that are not stopped by innate immunity alone. Failure of innate immunity is one of the alarms that activate adaptive immune mechanisms and thus these systems are tightly interlinked. Furthermore, after a first encounter with a pathogen, adaptive immunity imparts immunological memory, which allows a more efficient response in future encounters with the same pathogen.

Elements of Innate and Adaptive Immunity

Innate immunity has standing and induced components. Standing components of innate immunity are in place continuously and respond immediately to challenges, and include barriers such as the skin, transport mechanisms to avoid colonization like the mucociliary escalator in the airways, and constitutive chemical defenses such as the acidity of the stomach or the complement proteins in the blood. Other responses of innate immunity are carried out by recruited immune cells and induced translational/transcriptional programs that alter the capabilities of the tissue in combating an invader within minutes to hours. Some induced responses in long-lived innate cells can result in modification of the innate immune system such that it can mount a better response to a similar pathogen in the future, but this is different than adaptive immunity mediated by B and T lymphocytes. In the case of B and T lymphocytes, the respective surface receptors undergo recombination such that each cell has a unique receptor. The component that is recognized by the receptor is referred to as the antigen. The entire naïve repertoire of billions of lymphocytes may contain only a 1000 cells specific for antigens corresponding to a small pathogen like a virus. These rare antigen specific cells must undergo several rounds of cell division in order to mount an effector response. After eradication of the infectious agent the number of cells is again reduced to an intermediate sized memory pool that can persist for many years. T cells do not recognize antigen directly, but instead recognize antigenic peptides presented on proteins of the major histocompatibility complex (MHC). T cells have powerful regulatory role in responses, with some direct effector functions, but equally or more powerful roles based on organizing responses by B cells and innate cells. B cells make high-affinity antibodies in a manner dependent on T cells for all the highly repetitive carbohydrate antigens. Plasma cells that develop from B cells secrete antibodies and can live for years following an appropriate initial stimulation.

Barriers and Tissue Cells

An often neglected aspect of innate immunity is that role of tissue cells in forming barriers and establishing environments in which infections can be isolated and destroyed. The barrier function of the keratinized epithelium of the skin is illustrated by the vulnerability of burn victims to infection, whereas the single cell layer of the gut epithelium stands between us and trillions of microorganisms. When kept in place our gut microbiota is beneficial, but if they breach the epithelial barrier the resulting systemic infection or sepsis can be devastating. Stromal cells also play critical roles in innate immunity as endothelial barriers and stromal networks control the access of innate cells such as neutrophils and monocytes to sites of infection.

Chemical Defenses

The innate immune system uses chemical warfare against invading microbes. One example of this is the nicotinamide

adenine dinucleotide phosphate (NADPH) oxidase of neutrophils and phagocytes. This system allows neutrophils and other activated innate cells to generate reactive oxygen species that are the biological equivalent of 'bleach' to kill microbes. This type of activity must be carefully controlled to avoid toxicity to the host.

Important chemical defenses also include antimicrobial peptides made at mucosal interfaces to control colonization and the complement cascade in the blood. These have direct toxicity to bacteria, often by disrupting membrane integrity.

Complement is an effector mechanism that was initially studied as a 'complement' to antibodies that imparted microbicidal activity following antigen recognition. Complement is a proenzyme (zymogen) cascade similar in this respect to the clotting cascade. A series of proteins that circulate in the blood as inactive pro-forms assemble on microbial surfaces into active 'convertases' that proteolyse downstream components to generate effector molecules. There are two major outcome of complement activation – the most important is that some of the small proteolytic fragments generated in forming the convertases are potent chemoattractants that recruit neutrophils and monocytes from the blood into the tissues. In addition, the 'terminal' complement components form pores on the surface of microbes and can directly kill bacteria. There are many steps to this pathway that allow for regulation. One characteristic of complement is that the cascade is activated at a low rate on any surface with appropriate attachment sites for highly reactive thioester groups. Host cells are protected from this spontaneous activation of the cascade by host proteins that inactivate the convertase or block formation of pores. Pathogens that lack these protective molecules are attacked – an example of what is referred to as 'missing self' recognition. Microbes can also activate the complement cascade based on mannan-binding proteins that target some microbial cell wall components and through antibodies.

Antimicrobial peptides and complement proteins are always present at some levels, but their production at surfaces (peptide) or in the liver (complement) is dramatically increased in the setting of inflammation. The increased production of complement and other antimicrobial peptides is known as the 'acute phase response.'

Sensing Mechanisms

Sensing mechanisms that use receptors specific for evolutionarily conserved pathogen-associated molecular patterns (PAMPs) or danger-associated molecular patterns (DAMPs) are central to innate immunity and are themselves evolutionarily ancient. The first insights into the molecular basis of pathogen recognition came from classical genetics. Mutants in structurally related proteins in flies (Toll) and mice (Toll-like receptors) are critical for defense against pathogens. There are now 10 Toll-like receptors (TLRs) in mammals that are coupled to activation of the nuclear factor- κ B (NF κ B) transcription factor family to orchestrate induced innate immunity and, as will be discussed below, the link between innate and adaptive immunity for many extracellular pathogens. TLRs are type I transmembrane proteins with extracellular domains that

possess a leucine rich repeat (LRR) that assembles into long, sickle shaped domains that undergo oligomerization in response to specific ligands. Subsets of TLRs operate to sense extracellular microbes at the cell surface with TLR 7 and 8 residing in endosomes to sense viral nucleic acids that are generated as viral particles are uncoated at acidic pH. The cytoplasmic domains of the TLRs possess motifs that undergo oligomerization with cytoplasmic adapters that link through myeloid differentiation primary response gene 88 (MyD88) to activation of NF- κ B and AP1 transcription factors. Viral nucleic acid recognition additionally leads to induction of type I interferon (IFN) (α/β) through interferon regulatory factors (IRF3/7). It has become clear that different signaling adapters are prelocalized in plasma membrane domains and endosomes such that a single plasma membrane TLR can generate different signals before and after endocytosis. Thus, the exact signal is dependent upon the compartment in which ligand is recognized (Kagan, 2012).

Cytoplasmic recognition of PAMPs is achieved through retinoic acid inducible gene I (RIG-I) like receptors (RLRs), nucleotide-binding oligomerization domain-like receptors (NLRs), and other sensors that are less characterized or remain to be identified. Upon binding viral RNA species through RNA helicase-like domains, the RLRs RIG-I and MDA5 associate with mitochondrial antiviral-signaling protein (MAVS) to activate antiviral transcriptional responses. MAVS localizes to mitochondrial surfaces to induce IRFs and NF- κ B transcription factors that mediate expression of type I IFN and other immune genes. Cytoplasmic bacteria and DNA viruses are sensed through the cytoplasmic receptor stimulator of interferon genes (STING) and other factors to generate type I interferon. DNA in the cytoplasm can be converted to cyclic GMP-AMP (cGAMP) by the cGAMP synthase (cGAS) to activate STING localized to the ER surface, subsequently activating similar transcription factors as MAVS. A variety of ligands have been demonstrated to activate LRR domain-containing NLRs, but how these ligands are generated under physiological situations and whether they are sensed through direct binding remains an area of active investigation. The NLR family members NOD1 and NOD2 can localize to the cytosolic surface of endosome and are activated by peptidoglycan motifs derived from internalized bacteria, such as following phagocytosis. NOD2 has been reported to bind RNA from viruses as well. NOD1 and NOD2 signal through the adaptor molecule RIP2, again activating NF- κ B, AP1, and IRF transcription factors. Other NLR family members, such as NOD-like receptor family pyrin domain-containing 3 (NLRP3), oligomerize into large complexes referred to as inflammasomes in the presence of flagellin, pore-forming toxins, adenosine triphosphate (ATP), extracellular glucose, monosodium urate crystals, and other signs of cellular distress. Upon activation, the inflammasome aggregates with pro-caspase-1 to induce auto-cleavage into the active caspase-1 form, which in turn cleaves pro-IL-1 β and IL-18 to generate the biologically active form of these cytokines.

Pathogens interfere with innate sensing mechanisms. For example, hepatitis C virus (HCV), which causes chronic infections in humans, has a protease, NS3-4A, that targets innate signaling adapters MAVS and TIR-domain-containing adapter-inducing interferon- β (TRIF) thus inactivates multiple innate

Figure 1 Viral immune evasion by targeting innate cytoplasmic sensor. The NS3-4A protease of hepatitis C-virus cleaves the mitochondrial antiviral-signaling protein, MAVS, releasing it from mitochondrial and mitochondrial-associated membranes. The hepatoma cells shown in this image express a reporter comprised of the MAVS transmembrane domain fused to red fluorescent protein and a nuclear localization sequence (Jones *et al.*, 2010). RFP is localized to the mitochondria in noninfected hepatocytes (white arrowhead), but is released from the mitochondria by the action of NS3-4A in hepatitis C-infected hepatocytes (blue arrow). Left-fluorescence signal in red overlaid on phase contrast micrograph to show relationship to cell morphology. Scale bar=50 μ m. Micrograph courtesy of Stephen M. Laidlaw and Lynn B. Dustin Right-Schematic of the MAVS-based construct and basis for RFP translocation (N=nuclear localization sequence).

sensing pathways. A sensor for *in vitro* detection of HCV infection has been constructed by linking red fluorescent protein with a nuclear localization sequence to MAVS (Jones *et al.*, 2010; Figure 1). The RFP localizes to mitochondria, the normal location of MAVS, in noninfected cells (white Arrowhead) and, after action of NS3-4A, to the nucleus in infected cells (blue Arrow). Even with this evasion mechanism, HCV-infected hepatocytes produce an innate response including the production of the cytokine interferon- λ , highlighting the depth of viral sensing mechanisms (Marukian *et al.*, 2011). NS3-4A also processes the viral polyprotein that shares a sequence motif with the host adapters and is targeted by a protease inhibitor that is part of a highly successful drug combination used to treat HCV.

Phagocytes and Their Receptors

Phagocytes include neutrophils, macrophages, and dendritic cells (DCs), which have the capacity to engulf and digest relatively large particles on the order of 1–10 μ m and even larger. In adults, these cells are generated from hematopoietic stem cells in the bone marrow. Phagocytosis can be activated by receptors that share structural features with T and B cell antigen receptors, in which case the process takes on characteristics of cell–cell interactions with specialized junctions referred to as phagocytic synapses. Phagocytes express many type of ‘scavenger’ receptors that allow them to participate in clearance of aged host proteins and cells or microbe-derived materials. Pathogens may also exploit phagocytes as a port of

entry to colonize the host. One example is the gram positive bacterium *Listeria monocytogenes*, which generates a number of interesting virulence factors. One is called listeriolysin O, which allows the bacterium to lyse the phagocytic vacuole and directly enter the phagocyte’s cytoplasm. A second virulence factor, called Act A, then induces dynamic actin polymerization by activating the Actin-related protein 2/3 complex to generate ‘actin rockets’ that allow *Listeria* to move from cell to cell without passing through the extracellular space, thus avoiding extracellular immune effectors. Due to their ability to take up extracellular particles, phagocytes such as macrophages and DCs are excellent antigen presenting cells (APCs) that activate lymphocytes. B cells are also potent APCs because they can internalize antigens bound to the B cell receptor, which is essentially a plasma membrane-bound antibody. Therefore, although phagocytosis can lead to destruction of internalized microbes, the process also functions as a bridge between innate and adaptive immunity.

Innate Lymphoid Cells

Innate lymphoid cells (ILC) look physically and, to some extent, transcriptionally like lymphocytes, but they lack antigen receptors. They develop in the bone marrow from hematopoietic progenitor cells and are found in the blood, lymphoid tissues, and peripheral tissue in small numbers compared to T and B lymphocytes. The best known of these cells are the natural killer (NK) cells as these are relatively abundant and have direct effector function in killing tumor cells and some

virally infected cells. In the current nomenclature system for these cells there are three broad types of ILC: the group 1 ILCs that express the master transcription factor Tbet and make the signature cytokine IFN- γ ; the group 2 ILCs that express high levels of the transcription factor GATA-3 and make the signature cytokine IL-5, IL-13, and amphiregulin; and group 3 ILCs that express the master transcription factor ROR γ t and make signature cytokines IL-17 and IL-22 (Spits *et al.*, 2013). Each group of ILCs can be further divided into specialized subsets that express different combinations of their signature cytokines and effector molecules. As becomes clear below, the types of ILC parallel the types of T cells and the three programs are currently believed to reflect the coordinated responses needed to respond to the three major categories of pathogens—type 1 being viruses and intracellular bacteria; type 2 being parasites; and type 3 being extracellular bacteria. As with T cells, the ability of ILC to kill is imparted by the master transcriptional regulator eomesodermin in combination with Tbet, which also reflects a major transcriptional difference between type 1 helper T cells and cytotoxic T cells. Perhaps due to their highly similar effector programs and extensive specialization for cell-mediated killing, NK cells and cytotoxic T cells are more transcriptionally related to each other than NK cells are to other ILCs (Best *et al.*, 2013).

Lymphocytes

Lymphocytes are the core of adaptive immunity and were so named because they are abundant in thoracic duct lymph – the common return path of lymph fluid from the tissues to the blood. Removal of lymphocytes from an animal through thoracic duct cannulation severely impairs adaptive ‘humoral’ and ‘cellular’ immune responses. Lymphocytes can be divided into two types as briefly mentioned above. B lymphocytes or B cells (B is for Bursa, the hematopoietic site in birds) develop in the bone marrow of mammals and their effector function is to develop into antibody-secreting cells referred to as plasma cells. T lymphocytes or T cells (T is for thymus) develop in the thymus (see lymphoid tissues below) and in the periphery they engage in cellular immunity. T helper cells produce cytokines that orchestrate antibody production and other aspects of the immune response, in many cases through direct cell–cell contact. The key common feature of T and B cells is that they both have antigen receptors that exist in pieces in the germline that need to be assembled by a somatic gene rearrangement process mediated in part by recombinase-activating genes that are expressed in two precise periods in B cell and T cell development corresponding to sequential recombination of two loci for each antigen receptor. Once the T cell antigen receptor (TCR) and BCR are made these cells undergo selection processes to eliminate auto-reactive cells (negative selection) and in the case of T cells a process of positive selection that ensures that T cells are predisposed to recognize appropriately processed antigens. Antigen processing is discussed in the context of DCs. In the thymus, both DCs and epithelial cells engage in the negative and positive selection processes with the thymocytes. The mature, selected B and T cells leave the primary lymphoid tissues to begin recirculation through the blood and secondary lymphoid tissues (see below).

Immunological Synapses

Adaptive immune responses require at least three different central cell types – DCs and the two types of lymphocytes. In order to be able to help B cells make antibodies, T cells must be ‘primed’ and this is most efficiently done by a DC. The priming process requires that the DC takes antigens into its endocytic pathway, and through partial proteolytic processing, generate peptides that bind the MHC proteins. Dendritic cells can introduce antigens taken up from outside the cell into two different types of MHC molecules. MHC class Ia molecules bind peptides in the endoplasmic reticulum that are generated in the cytoplasm by the proteasome. Dendritic cells are able to ‘cross-present’ in that they can introduce proteins that are taken into the endocytic pathway into the cytoplasm to generate peptides that are then presented on MHC class Ia. In other cell types, the presentation of a peptide derived from an infectious agent on MHC class Ia would indicate that the cell had the pathogen in its cytoplasm and it could thus become a target for killing, but DCs have the ability to present peptides on MHC class Ia even when they are not infected directly (Bevan, 2006). MHC class II molecules bind peptides in the endocytic pathway because they are blocked from binding peptides in the endoplasmic reticulum by a chaperone protein called invariant chain. MHC proteins are germline encoded, so they are fixed within an individual, but they are highly polymorphic across animal populations. This is important because the six MHC class Ia and six MHC class II genes in each individual human, for example, may not cover all antigenic peptides and this diversity in a population can be important for survival of a species faced with an epidemic of a particular deadly pathogen like *Variola major* (smallpox virus) or *Yersinia pestis* (bubonic plague bacterium). MHC class Ib genes include β 2 microglobulin-associated peptide-binding proteins like H2-M3 and Qa-1 in the mouse and human leukocyte antigen (HLA-E) in human. HLA-E binds signal peptides derived from MHC class Ia proteins and serves as a ligand for inhibitory receptor CD94/NKG2A on NK cells and CD8⁺ T cells, sensing pathogen interference with MHC class Ia protein expression. This is a specific example of missing self-recognition – the manner in which NK cells sense the presence of viruses that interfere with MHC class Ia expression to avoid having infected cells killed by cytotoxic T cells (Karre, 2008). The cell biology of MHC class I and II presentation has been intensively studied, but surprisingly, the underlying mechanisms that allow cross-presentation by DCs are controversial.

Once a peptide–MHC complex is expressed on an APC, it may potentially activate a T cell with a complementary TCR. This process requires close membrane apposition during recognition in the form of an immunological synapse or a kinapse. The TCR and peptide–MHC will span about 15 nm when engaged and this close proximity is facilitated by adhesion molecules in close coordination with the actin cytoskeleton. The TCR interaction with the peptide–MHC complex is weak in solution, but seems perfectly adapted to operate in a synaptic junction. The basic chemistry and physics of this environment is an area of active study. The downstream signal transduction process is well defined, although there are many nuances to this including how distinct co-stimulatory signals are integrated with TCR signals. We would define the

immunological synapse as a (1) stationary cell–cell junction, (2) built from bona fide adhesion molecules, (3) with contiguous membranes, and (4) vectorial communication by secretion (Dustin and Colman, 2002; Dustin *et al.*, 1998). It has been observed *in vitro* and *in vivo* that T cells can recognize antigen through a stationary or moving junction (Dustin, 2007).

Thus we have stationary synapses and mobile kinapses (Box 1). Early work on stationary junctions defined three compartments referred to as supramolecular activation clusters (SMACs) (Freiberg *et al.*, 2002; Monks *et al.*, 1998). Analysis of the F-actin dynamics in the immunological synapse suggests that the distal SMAC (dSMAC) corresponds to a lamellipodium, the peripheral SMAC (pSMAC) to a lamella and the central SMAC (cSMAC) to the uropod of a migrating mesenchymal cell (Sims *et al.*, 2007; Yi *et al.*, 2012). The major adhesion molecules on human lymphocytes are CD2, which is a member of the signaling lymphocyte activation molecule (SLAM) family, and lymphocyte function-associated antigen-1 (LFA-1), which is a member of the integrin family (Springer,

1990). The ligand for CD2 is CD58 (also called LFA-3) and the ligand for LFA-1 is intercellular adhesion molecule-1 (ICAM-1). These molecules concentrate in different compartments of the pSMAC during immunological synapse formation, whereas the TCR and co-stimulatory molecules like CD28 accumulate first in microclusters (MC) that form in the dSMAC and traverse the pSMAC in gaps within the adhesion ring to converge on the cSMAC. In the cSMAC ubiquitinated TCR are segregated from the CD28 signaling complexes forming two compartments by the endosomal sorting complexes required for transport (ESCRT) – an endo cSMAC that is active in signaling and an exo-cSMAC that is a site of TCR signal termination and either endocytosis for degradation or budding of extracellular vesicles (EV) into the synaptic cleft for transfer to the APC (Choudhuri *et al.*, 2014). In the stationary synapse, the motile machinery of the lamellipodium-like dSMAC is prevented from moving the T cell by the overall radial symmetry, which results in balanced forces and focusing of molecules toward the center. The conversion of a synapse to a kinapse requires a symmetry breaking event in the pSMAC,

Box 1 Model immunological synapse

(a) Schematic of T cell–APC interface with a centralized immunological synapse (b) and (c). Front-on view of model for central synapse organization and how this related to kinapse – a mobile junction with similar compartments. (d) Schematics with zones showing a small subset of adhesion and recognition molecules involved. Color code: black, F-actin lamellipodium; blue, LFA-1-ICAM-1 adhesion; red, TCR-MHC antigen recognition; and green, CD28-CD80 costim SMACs are labeled. Note that the cSMAC is an intensive site for membrane trafficking including a directed budding of T cell receptor enriched extracellular microvesicles in the immunological synapse

which is the force generating element of the synapse/kinapse system (Sims *et al.*, 2007). In the kinapse, the TCR microclusters form similarly, but the T cell continues to move and the TCR enriched extracellular vesicles (EV) are left behind with the antigen presenting surface (Choudhuri *et al.*, 2014). There is also important vesicular trafficking of TCR that contributes to synapse formation (Das *et al.*, 2004).

This model for formation of a radially symmetric immunological synapse is largely based on work with supported planar bilayers rather than live APC. Not all live APC induce T cells to form the radially organized SMACs, yet T cells can still form stationary synapses with these APC. A prominent example is DCs, which forms multifocal synapses that lack obvious radial symmetry in many studies (Brossard *et al.*, 2005; Gunzer *et al.*, 2004; Tseng *et al.*, 2008). This has been observed with multiple DC types including splenic DC and bone marrow-derived DC generated with granulocyte-macrophage colony stimulating factor and IL-4. This issue is explored in two other chapters of this encyclopedia. Studies by Wulfigg and colleagues define a deep lamellar F-actin component even in the T-B junctions that do form SMACs (Roybal *et al.*, 2013). Parallel work from Carman and colleagues define multiple invadopodia-like protrusions (ILP) that push into endothelial APC to form a multifocal synapse (Sage *et al.*, 2012). Recently we have found working with Carman that TCR microclusters formed on supported lipid bilayers have similar molecular machinery to ILPs, particularly requiring Wiscott-Aldrich syndrome protein (WASP) and containing phosphorylated hematopoietic lineage cell-specific protein 1 (HS1) (Kumari *et al.*, 2015). Figure 2 suggests a unifying model in which a similarly equipped T cell can interact with two different APC to

form a radially symmetric synapse based on MC or a multifocal synapse based on ILP. While the multifocal synapse lacks radial symmetry, the junction is still stationary because the ILP protrusions effectively entangle the T cell and APC. While symmetry break is required for conversion of a MC type synapse to a kinapse, the ILPs would need to be withdrawn to allow the T cell to disengage from the ILP type synapse. We know that TCR signaling by MC is terminated in ~ 2 min in the cSMAC, but the natural lifetime of the ILP and how they are turned over remains to be determined.

Antigens presented on MHC class Ia are recognized by CD8⁺ cytotoxic T cell precursors that undergo priming on DCs, expand rapidly and then leave the secondary lymphoid tissue (assuming this is not the site of infection) and migrate through the blood to sites of infection where they extravasate and kill peptide-MHC expressing cells. The radially symmetric central synapses have a well-defined secretory domain and may be the most effective at killing (Stinchcombe *et al.*, 2001). Killing is threefold more effective through a stationary synapse compared to a kinapse (Beal *et al.*, 2008). They also make cytokines and chemokines and these can recruit additional cells that support pathogen eradication and the transition to repair. The number of CD8 T cells then contracts and if antigen is cleared a population of memory cells remains to respond more effectively to future encounters. If the infection is not resolved then chronic infection may result with some balance between control of the infection and immunopathology resulting from the chronic immune response.

Antigenic peptides presented on MHC class II complexes are recognized by CD4⁺ helper T cells that undergo priming on DCs, expand and then differentiate into diverse helper T cell

Figure 2 Immunological synapse formation on stiff and soft APC. TCR/CD28 signaling is associated with central clusters that are transported by F-actin and myosin II-mediated centripetal transport on round, relatively stiff APC like B cells (*in vitro*). Paradoxically, softer cells in which the TCR clusters can protrude through the cortical actin of APC will not permit lateral transport and instead the dominant F-actin flow is away from the synapse, rather than toward the center. In this case the TCR/CD28 signaling foci are multifocal.

types. The helper types Th1, Th2, and Th17 correspond roughly to the type 1, 2, and 3 ILC, respectively. A fourth subset of helper T cells, T follicular helper cells, or Tfh cells, express the chemokine receptor CXCR5 and migrate to B cell follicles to provide contact dependent help to B cells to form germinal centers. Engagement of the ICOS co-stimulatory receptor further reinforces this pathway (Liu *et al.*, 2014). Germinal center B cells engage in cycles of interaction with Tfh in the 'light zone' and cell division and somatic hypermutation and class switching in the 'dark zone' of the germinal center. The other Th types influence the process of class switching and generate effector cells that migrate to the site of infection to orchestrate the immune response. However, the innate recognition of the pathogen by DCs and other tissue cells, as well as some information associated with peptide-MHC levels, determine which effector type the non-follicular Th assume. Type I interferon and IL-12 stimulated by viral and intracellular bacterial infection promote the differentiation to Th1 cells that make interferon- γ and promote macrophage activation and promote B cell class switching to Fc receptor-binding cytotoxic antibody isotypes. Proteases and other signatures associated with parasitic infection favor generation of Th2 cells, which make IL-4, IL-5, and IL-13 and promote antiparasitic responses in tissues and isotype switching to IgE. In the presence of inflammasome activation leading to IL-1 β and IL-6 production that favor the differentiation Th17 cells, which make cytokines IL-17 and IL-22 that induce neutrophil recruiting chemokines and reinforce epithelial barrier function as a defense against extracellular bacterial infections. These phenotypes can be quite plastic with cells making both IFN- γ and IL-17 observed in some immune response contexts. CD4 T cell memory may thus be more diverse due to the different effector types. Th cells also receive inputs from a number of TNF receptor family members that influence effector function and can promote memory development across different helper types. Due to the antigen specificity of these effector functions, Th may be able to act more aggressively than innate like cells because their activity can be more precisely controlled in both space and time.

A subset of CD4⁺ T cells are referred to as regulatory T cells that express the master transcription factor FoxP3. These cells play an essential role in maintaining immune homeostasis, at least in part by managing the immunogenicity of DCs through trans-endocytosis, a process in which the regulatory T cells strip DCs of co-stimulatory molecules that are necessary for activating other T cells. A population of regulatory T cells is generated in the thymus and another population is generated in the periphery from naïve CD4⁺ T cells in response to self-antigens or to control responses to benign environmental antigens (Weiss *et al.*, 2012). The induction of regulatory T cells *in vitro* can be achieved with high concentrations of transforming growth factor- β , which is also one of the effector molecules employed by these cells to regulate other immune cells. Regulatory T cells are marked by high expression of the CD25 subunit of the growth promoting cytokine IL-2 receptor. This is of functional relevance as FoxP3⁺ regulatory T cells require IL-2 to survive, and one of the ways in which they suppress growth and differentiation of effector T cells is to consume IL-2 in a competitive manner (Furtado *et al.*, 2002). FoxP3⁺ regulatory T cells seem to shadow the various effector

helper types such that there are regulatory T cells in all tissue compartments including the germinal centers. There is evidence that CD8⁺ T cells can also be involved in regulation of immune responses, but this may be a more general feedback process related to killing. Individuals with defects in killing mechanisms shared by CD8⁺ T cells and NK cells are vulnerable to hemophagocytic syndrome, which is immunopathology caused by uncontrolled activation of phagocytes (Menasche *et al.*, 2005). A specific subpopulation of CD8 T cells that is restricted by the Qa1/HLA-E MHC class Ib molecules are also involved in regulation of recall responses by CD4⁺ T cells, probably by direct killing of the the Qa-1/HLA-E positive T cells (Kim and Cantor, 2011).

Lymphoid Tissues

Lymphoid tissues (LT) are specialized for development or function of immune cells. There are three types of LT: primary LT where developmental steps takes place, secondary LT that are involved in steady state surveillance, and tertiary LT that are generated *de novo* to support local immune responses associated with chronic infection or autoimmunity. In mammals, the major primary lymphoid tissues are the bone marrow and thymus. The bone marrow functions in generation of red blood cells, myeloid cells of innate immunity, and B lymphocytes. The output of neutrophils is the most intensive activity and perhaps also the most responsive process to signals associated with inflammation. Production of B cells is tightly linked to the rearrangement of antibody genes. T cell progenitors leave the bone marrow and colonize the thymus. The thymus is an organ that sits on top of the heart and has extensive epithelial components that are organized within the cortical and medullary regions with post-capillary venules at the cortico-medullary junction. Developing T cells, called thymocytes, rearrange the TCR genes in the cortex and initiate selection processes. Selection is completed in the medulla, where specialized epithelial cells express the auto-immune regulator transcription factor (AIRE), which allows these cells to express large segments of tissue-specific genes in the thymus to facilitate negative selection or thymic regulatory T cell development in response to self-antigens (Anderson *et al.*, 2002).

Secondary lymphoid tissues include the lymph nodes, spleen, tonsils, Peyer's patches, and bronchi associated lymphoid tissues. Lymphoid tissue development depends upon a type 3 ILC referred to as a lymphoid tissue inducer cell, which uses TNF family cytokines such as lymphotoxin- β to induced reorganization of at least four stromal cell types to generate distinct, but adjacent T cell and B cell zones with site specific entry points for antigens and entry and exit points for DCs and lymphocytes. T and B cell zones are defined by distinct stromal cells that make chemoattractants CCL19 and CCL21 for T cell zones and CXCL13 for B cell zones. Within the T cell zones the fibroblastic reticular cells (FRC) form a CCL19 positive network that drives rapid migration in the steady state. This brings DCs that form an overlying network on the FRC in contact with ~1000 T cells per hour. Within the B cell zones, also known as follicles, the follicular dendritic cells (FDC) form a CXCL13 positive network for follicular B

cell migration and germinal center formation. The FDC in the light zone of the germinal center because further specialized and express complement receptor such that they can capture and present antigen containing immune complexes to provide a source of antigen to drive the necessary mutation/selection cycles in the germinal center (Victoria and Nussenzweig, 2012).

The lymph nodes are closely associated with the blood and lymphatic vasculature such that they effectively create a tissue island within an expanded lymphatic vessel that is supported by a blood capillary network with specialized post-capillary venules. Lymph nodes samples antigens from the lymph draining most vascularized tissues and organs and are thus important sites for function of subcutaneous and intramuscular injected vaccines. These can reach the lymph nodes as soluble antigens, immune complexes (with antibodies and complement), or associated with migratory DCs. The secondary lymphoid tissues of the spleen are referred to as the white pulp and form as a periarteriolar lymphatic sheath. Arterioles from this central arterioles open into the marginal zone and red pulp sinuses. Marginal zone B cells are specialized to shuttle antigens from the marginal zone to follicular DCs. The FDCs then to make these accessible to capture by BCR of follicular and germinal center B cells, which process these antigens to peptide-MHC complexes for presentation to follicular helper T cells. Antigens reach the T cell zone of the spleen associated with DCs that migrate from the marginal zone. The Peyer's patches, tonsils, and bronchi associated lymphoid tissues samples antigens across the mucosal epithelium. The best studied mechanism involves M-cells over the epithelium of the Peyer's patch that allows sampling of food and microbial components from the small intestine and transfer of these to DCs.

T and B cells enter lymph nodes from the blood through high endothelial post-capillary venules that express peripheral lymph node addressin (PNAd), chemokine CCL21, and ICAM-1. T and B lymphocyte enter lymph nodes by initially undergoing rolling adhesion in blood flow using CD62L to latch onto PNAd, then being activated by chemokine receptor CCR7 interaction with chemokine CCL21 that activates LFA-1 mediated adhesion to ICAM-1 to stabilize interaction with the endothelial cells and allow extravasation. This is referred to as the multistep paradigm for blood cell homing (Springer, 1994). Variations on this are used for entry into other lymphoid tissues. For example, in the gut, the role of PNAd and ICAM-1 is largely replaced by the mucosal addressin cell adhesion molecule (MAdCAM), which is a ligand for the lymphocyte Peyer's patch adhesion molecule (LPAM-1), which is a distinct integrin family member from LFA-1. Entry into the spleen is more complex and involves capture in the red pulp venous sinuses and migration through bridging channels into the T cell zones, or migration through the marginal zone directly into follicles for B cells. Once T and B cells have crossed the endothelium, they migrate toward the respective zones.

Tertiary lymphoid tissues emerge in sites of chronic immune responses, including in autoimmunity. Well known examples include the lymphoid aggregates in synovium of patients with rheumatoid arthritis and chronic infections such as *Helicobacter pylori*. In the cancer setting, the presence of

tertiary lymphoid tissue in colorectal cancer is a good prognostic indicator. On the other hand, stromal cells making CXCL12 in pancreatic cancer may divert tumor infiltrating lymphocytes from mounting effective responses.

Stromal cells can also participate directly in regulation of immune responses. FRC can suppress immune responses through interferon- γ stimulated nitric oxide production (Lukacs-Kornek *et al.*, 2011). On the other hand, endothelial cells can up-regulate MHC class II in response to interferon- γ and participate in activation of helper T cells.

Evolution

Innate immunity is an ancient process that is common to all multicellular organisms. Adaptive immunity based on immunoglobulin superfamily antigen receptors is shared by jawed fish, reptiles, amphibians, birds, and mammals. Interestingly, larval forms of jawless fish possess an adaptive immune system based on somatic cell gene rearrangement of LRR-based receptors referred to as variable lymphocyte receptors (VLRs) (Boehm *et al.*, 2012). There are two types of VLR expressing lymphocytes that appear to correspond to B cell-like and T cell-like roles, although the equivalent of an MHC for the TCR-like VLR has not been identified. Thus, the evolution of adaptive immune systems with humoral and cellular components has devolved at least twice on top of existing innate components with cells that have specialized secretory and cellular effector functions.

Perspective

The immune system provides a treasure trove for functional cell biology. This is in part because in this system pathogens act as our teachers and call our attention to functionally significant and nonredundant elements in the immune system that are often shared with other developmental and homeostatic processes in the body. It has also become clear that improvements in treatment for autoimmune diseases and better immunotherapies will only be possible with a better understanding of the functional cell biology of the immune system. This section of the *Encyclopedia of Cell Biology* defines our current knowledge about cellular aspects of the immune system, and certainly also exposes gaps in knowledge that can be filled using tools of cell biology.

Introduction

All jawed vertebrates have lymphoid organs like the thymus and spleen and genes encoding T and B cell receptor chains. T lymphocytes mature in the thymus and play a central role in cellular immunity, by regulating other immune cells and by differentiating into cytotoxic effector cells that can also make cytokines. T cells express a clonally distributed receptor composed of two main chains, $\alpha\beta$ or $\gamma\delta$ T-cell receptor (TCR). Ligands of $\gamma\delta$ T cell receptors are not well-characterized and this article will focus mainly on $\alpha\beta$ T lymphocytes. With the exception of a few TCRs, which utilize invariant $\alpha\beta$ TCR to recognize bacterial glycolipids associated to CD1d or sense bacterial metabolites associated with MR1, most ligands of $\alpha\beta$ TCRs are peptides (p) associated to class I and class II major histocompatibility molecules (p-MHC). Major histocompatibility complex (MHC) class I binds peptides derived from endogenously synthesized proteins, whereas MHC class II presents peptides derived from proteins taken into the cell from the extracellular space. The $\alpha\beta$ TCR endows T cells with the ability to recognize foreign peptide antigens (e.g., from bacteria, virus, or tumor origin) with high sensitivity while being tolerant to the individual self-peptide antigens in complex with the same MHC molecules. How does the cellular machinery recognize and tolerate self-p-MHC complexes, and differentiate them from foreign p-MHC complexes to trigger the necessary immunological responses?

The TCR belongs to a family of immunoreceptors which also include the B-cell receptor (BCR) and the receptors for the Fc portion of immunoglobulins (FcR). These receptors share a similar membrane organization with multiple transmembrane chains having distinct ligand-binding and signal transduction functions. No intrinsic enzymatic activity is associated with

these receptors. Instead, non-covalently associated kinases from the SRC and spleen tyrosine kinase (SYK) families initiate signaling cascades and transcriptional programs associated with T cell activation and differentiation. Signal initiation requires the conversion of the initial ligand recognition event into an intracellular biochemical modification. This signal conversion step involves the assembly of a large complex of multifunctional proteins in the vicinity of the TCR, collectively designed as TCR signalosome. The signaling code used to transform the properties of the ligand into biochemical signals has to account for the high discriminatory potential of the TCR for foreign and self-antigens, i.e., ligands of similar structure. The coding, conversion, and transmission of receptor–ligand properties by cell-surface receptors are problems of general interest in cell biology. Unlike most receptors, the TCR is not germline-encoded due to DNA recombination events occurring at the TCR locus during T cell development in the thymus. As a result, each of the millions of different TCRs expressed by each individual does not recognize one single ligand, but a limited series of p-MHC ligands with different affinities. The coding of the information associated with these ligands by the TCR signalosome is thus the focus of much interest and is the object of this article.

The TCR and Its Ligands: Structural and Functional Topology

The TCR, a Tyrosine Kinase-Coupled Receptor

Receptors that signal by activating tyrosine kinase activities either contain a kinase domain within their cytoplasmic tail (receptor tyrosine kinases) or are coupled to cytosolic tyrosine

Figure 1 EGF receptor activation involves both conformational and oligomerization events. EGF binding induces a conformational change of the receptor (1), which exposes a dimerization loop (CR1) (2) required for receptor oligomerization (3). Full activation requires additional conformational changes within the kinase domains following dimerization (4). Adapted with permission from Ward, C.W., Lawrence, M.C., Streltsov, V.A., *et al.*, 2007. The insulin and EGF receptor structures: New insights into ligand-induced receptor activation. Trends in Biochemical Sciences 32, 129–137. © 2007 Elsevier.

kinases (tyrosine kinase-linked receptors). The TCR belongs to the latter category. Numerous studies explored the signal transduction properties of these receptors and revealed multiple signaling mechanisms.

Activation by dimerization is the most common signal transduction mechanism. Dimerization usually puts into close proximity the kinase domains within the cytoplasmic tails. *Trans*-phosphorylation events then lead to full activation of the kinase activity and additional phosphorylation events nucleate the recruitment of multiprotein signaling complexes. This mechanism applies to platelet derived and fibroblast growth factor receptors, to name two examples. Conformational changes can also participate in signal transduction. For instance, epidermal growth factor (EGF) induces a conformational change in the extracellular domain of its receptor and this change is required for dimerization and activation (Figure 1; Ward *et al.*, 2007). Finally, the insulin receptor exists as an inactive dimer and ligand induced conformational changes alter the proximity of the kinases domains to allow *trans*-phosphorylation. Altogether, these examples illustrate that the signaling code used by cell-surface receptors is complex and can involve both dimerization and conformational events.

Subunit Composition, Stoichiometry, and Valency of the TCR

The TCR is composed of two ligand-binding chains (α and β or γ and δ) and six CD3 chains. The CD3 subunits form three dimers ($\delta\epsilon$, $\gamma\epsilon$, and $\zeta\zeta$) and are required for cell-surface expression and intracellular signaling (Malissen *et al.*, 1999). The TCR complex is thus characterized by spatially separated ligand-binding and signal transduction subunits. The assembly of the receptor relies on interactions between the extracellular immunoglobulin domains of the CD3 subunits and $\alpha\beta$ TCR chains, and the presence of nine conserved residues within the transmembrane domains (Call and Wucherpfennig, 2007; Figure 2). None of the TCR receptor chains have intrinsic kinase activity. However, SRC-family kinases are associated with CD8 and CD4 TCR co-receptors. These co-receptors bind

to non-polymorphic epitopes on MHC class I and class II molecules, respectively, upon recognition of activating ligands by the TCR. Co-receptors thus couple the TCR to SRC kinases by co-localizing them in the vicinity of the TCR chains.

Despite the absence of enzymatic activity, CD3 chains all contain immunoreceptor tyrosine-based activation motif(s) (ITAMs), which are also present in other immunoreceptors (Figure 3). With 2 tyrosines per ITAM and 10 ITAM motifs per TCR complex, there are a total of 20 tyrosine residues susceptible to become phosphorylated upon TCR triggering. The combinatorial mutation of the ITAMs of the TCR demonstrated their crucial importance for T cell development and functions (Holst *et al.*, 2008).

The stoichiometry of the receptor is a crucial parameter as it determines the number of ligand-binding subunits per receptor complex, i.e., the receptor valency. The stoichiometry of the TCR was generally thought to be one $\alpha\beta$ TCR heterodimer and three CD3 dimers: $\zeta\zeta$, $\delta\epsilon$, and $\gamma\epsilon$ (Call and Wucherpfennig, 2005). This monovalent model largely relies on the biochemical analysis of TCR complexes neosynthesized *in vitro* on microsomes (Call *et al.*, 2004), but also on multiple other experimental approaches (reviewed in Schamel and Alarcon, 2013). Other studies proposed bivalent or multivalent models for the TCR complex, based on the measurement of sedimentation coefficients, native gel electrophoresis, immunological analysis of detergent solubilized receptors, and the observation of higher order TCR oligomers by electron microscopy (reviewed in Schamel and Alarcon, 2013). An even higher level of organization has been suggested by analysis of 'protein islands' containing hundreds of TCR in domains ranging from 30 nm to 300 nm – preexisting prior to activation events. However, analysis of TCR diffusion in quiescent T cells suggests that each TCR moves independently. It has been suggested that some of the discrepancies may arise from changes in TCR organization at different stages of T cell differentiation, for example, that the TCR complex is differently organized in T cells that have only recognized self-antigens (naïve) and those that have been previously activated by a

Figure 2 Structure of the $\alpha\beta$ TCR. TCR α and β chains only contain five amino acids in their cytoplasmic domains. Intracellular signals are transduced by $\alpha\beta$ TCR-associated CD3 subunits. Their interaction with α and β chains involves acidic (red) and basic residues (blue) in the transmembrane domains of CD3 and $\alpha\beta$ TCR chains. higher affinity foreign antigen (memory). A general solution to the long-standing question of the stoichiometry of the TCR remains to be identified.

Properties of TCR Ligands

The ability of $\alpha\beta$ TCRs to recognize a diverse universe of pathogens is based on peptides non-covalently associated with class I and class II MHC molecules, respectively recognized by CD8⁺ and CD4⁺ T cells. There are multiple genes encoding class I and class II MHC proteins and each of these genes has a large number of alleles across a population. As most of the allelic diversity is focused on the pocket binding the peptides (Bjorkman *et al.*, 1987), the combination of MHC molecules restricts the repertoire of peptides that bind to each individual's

MHC molecules and thus largely defines the immunological self and the ability to respond to pathogens.

In the event of an infection, peptides generated by proteolysis of the proteins of the pathogen are loaded onto MHC molecules in a similar manner to endogenous peptides. The number of MHC molecules forming complexes with foreign peptides during an infection is estimated to range from 10² to 10⁴, thus only representing 0.1–10% of the total number of MHC molecules expressed on the cell surface. Therefore, the first property of activating TCR ligands is their low representation on the cell surface, in comparison with endogenous p-MHC ligands.

The second property of these ligands is their structural complexity. Unlike most conventional receptors, TCRs recognize ligands that they have not previously encountered. In most cases, only a few side chains of the peptide are exposed to the solvent above the peptide binding groove defined by the two MHC helices, whereas about half the side chains serve as anchors that bind the peptide to the MHC (Figure 4; Stern and Wiley, 1994). The distinction between self- and foreign-p-MHC complexes thus relies on a few specific bonds with exposed side chains of the peptide plus small changes in the positioning of the peptide backbone due to differences in anchoring interactions.

A third property of TCR ligands is their low affinity for their cognate receptor, with K_D ranging from 1 μ M to effectively unmeasurable for some self-p-MHC (> 1 mM) (Davis *et al.*, 1998). This affinity range is much lower than the affinity range for many immunoglobulins and their ligands, which undergo a process of 'somatic hypermutation' to achieve K_D less than 1 nM. TCR undergo no similar mutation process to achieve higher affinity and engineering of high affinity TCR:p-MHC for tumor immunotherapy has yielded mixed results. TCR:p-MHC interactions have an affinity range that is typical for adhesion receptors, where confinement of interactions in the interface leads to efficient binding in this affinity range. Thus, the observed physiological TCR:p-MHC affinity range is optimal, but

there are still many questions about how they operate in natural immune responses.

Finally, TCR ligands also have this intriguing property of inducing very pleiotropic responses in T cells, ranging from survival to apoptosis, partial or full activation, and acquisition of various effector functions (cytotoxicity, cytokine production, proliferation, and differentiation). Although these decisions are influenced by the context of the activation event, ligand properties also impact on the kinetics, magnitude, and qualitative nature of the response (reviewed in [Corse et al., 2011](#)). As an example, the polarization of CD4⁺ T cells toward a Th1 (characterized by interferon- γ , interleukin (IL)-2, tumor necrosis factor production, and cell-mediated immunity) versus Th2 effector phenotype (characterized by IL-4, IL-5, IL-10, and IL-13 production and strong antibody responses) is

Figure 4 3D-structure of a TCR:p-MHC complex. The recognition by the TCR (blue) involves interactions with the MHC molecule (orange) and with the few exposed side chains of the peptide (displayed in ball and stick). Adapted from Zoete, V., Irving, M., Ferber, M., Cuendet, M. A., Michelin, O., 2013. Structure-based, rational design of T cell receptors. *Frontiers in Immunology* 4, 268.

strongly influenced by the strength of TCR:p-MHC interactions ([Van Panhuys et al., 2014](#)).

Altogether, the unique properties of activating TCR ligands raise the following question: what is the signaling code used by the TCR signalosome to convert and propagate the information associated with ligand recognition?

The Signaling Code Used by the TCR Signalosome to Convert Extracellular Signals into Biological Responses

The Kinetic Model of T Cell Activation

Thermodynamic and kinetic parameters of TCR:p-MHC interactions are known for several pairs of TCR:p-MHC complexes ([Figure 5](#); [Kalergis et al., 2001](#); [Davis et al., 1998](#)).

Combined with the observation that TCR cross-linking via anti-TCR antibodies induces T cell activation ([Kaye et al., 1983](#)), these data point to a kinetic model of T cell activation in which the K_D of the TCR:p-MHC interaction, or more accurately the half-life of the complex ($t_{1/2}$), dictates the degree of TCR clustering with its co-receptors and associated kinases, and thus T cell activation ([Choudhuri and Van Der Merwe, 2007](#); [Figure 6](#)). Note that TCR clustering could involve either the aggregation of monovalent TCR complexes and/or multivalent preformed TCR nanoclusters into larger microclusters.

Supporting this model, quasi-elastic light scattering measurements of the hydrodynamic radius of TCR:p-MHC complexes in solution showed that recognition of the cognate p-MHC ligand by the TCR leads to oligomerization in solution, an event which was strictly dependent on the presence of a specific activating peptide ([Reich et al., 1997](#)). Accordingly, the kinetics of the TCR:p-MHC interaction measured by surface plasmon resonance are compatible with a dimerization model ([Alam et al., 1999](#)). Finally, dynamic imaging of receptor complexes during T cell activation also confirmed the

Figure 5 Thermodynamic and kinetic parameters of TCR:p-MHC interactions. (a) Thermodynamic and kinetic dissociation constants for two TCRs and their ligands (reviewed in [Davis et al., 1998](#)). Ligands are categorized according to their functional impact: strong and weak agonists induce full and partial T cell responses, respectively, whereas antagonists inhibit agonist responses. The substitution of one single residue in the peptide (e.g., MCC 102S/E^k) converts the agonist into a partial agonist with biological responses attenuated by a 20 000-fold factor, while the $t_{1/2}$ of the interaction decreases from 11 to 2 s, i.e., only by a 5-fold factor. (b) Correlation between TCR:p-MHC half-lives and T cell activation. Each dot represents a TCR:p-MHC complex. Adapted with permission from Kalergis, A.M., Boucheron, N., Doucey, M.A., et al., 2001. Efficient T cell activation requires an optimal dwell-time of interaction between the TCR and the pMHC complex. *Nature Immunology* 2, 229–234. © 2001 Elsevier.

Figure 6 Kinetic model of T cell activation. In this model, TCR aggregation is dictated by thermodynamic and kinetic properties of the TCR:p-MHC interaction. Longer half-lives favor the recruitment of co-receptor associated kinases and ITAM phosphorylation. Adapted with permission from Choudhuri, K., Van Der Merwe, P.A., 2007. Molecular mechanisms involved in T cell receptor triggering. *Seminars in Immunology* 19, 255–261. © 2007 Elsevier.

formation of supramolecular activation clusters or SMACs (Campi *et al.*, 2005; Varma *et al.*, 2006).

In this kinetic model, the signaling code is thus based on the kinetic parameters of the TCR:p-MHC interaction, which translate into various degrees of TCR and co-receptor clustering, and thus various levels of SRC kinase activation and downstream ITAM phosphorylation. This model explains well why the distance between TCR ligands, but not their orientation, impacts on T cell activation (Cochran *et al.*, 2001; Delcassian *et al.*, 2013).

However, this model does not account for the sensitivity of T cells since 90–99.9% of p-MHC complexes are endogenous and not activating p-MHC, and the probability of TCR oligomerization is thus very low. As a potential explanation to this paradox, the oligomerization property of TCR:p-MHC complexes observed in solution could favor TCR clustering. Another explanation resides in the observation that activating dimerization events can involve TCRs that do not recognize the activating p-MHC. In this pseudo-dimer model, the low affinity of the interaction between the co-receptor and MHC allows for its dissociation from the activating p-MHC and rebinding to a neighboring endogenous p-MHC engaged with another TCR. These pseudo-dimers of activating/endogenous p-MHC complexes induce activating events, whereas monomers or dimers of endogenous p-MHC do not (Krogsgaard *et al.*, 2005). Finally, clustering events take place in the 2D-plane of the cellular membrane and more particularly in the delimited area corresponding to the zone of contact between two cells or immunological synapse (Dustin and Depoil, 2011). This synapse locally concentrates TCR:p-MHC complexes and thus increases the probability of TCR clustering events. Altogether, these various mechanisms explain why a low number or even a single activating TCR:p-MHC interaction can induce TCR oligomerization and drive T cell activation.

The fact that the TCR:p-MHC interaction takes place in a dynamic interface between two cells also provides an opportunity to use physical forces to sharpen ligand discrimination (Klotzsch and Schutz, 2013). A critical parameter in this context is the response of the kinetic off-rate to applied forces. Recently, Liu *et al.* (2014) have found that agonist TCR:p-MHC form 'catch-bonds,' which become stronger when a force is applied. The structural basis of this behavior is not known, but this could explain situations in which solution measurements

Figure 7 The kinetic-segregation model of T cell activation. The formation of TCR:p-MHC complexes requires the apposition of the two cell membranes at a distance of 15 nm. This binding event induces the spatial segregation of proteins with large extracellular domains, like CD45, from the synaptic contact. This local exclusion tips the phosphatase-kinase balance in favor of kinases, and triggers ITAM phosphorylation. Adapted with permission from Choudhuri, K., Wiseman, D., Brown, M.H., *et al.*, 2005. T-cell receptor triggering is critically dependent on the dimensions of its peptide-MHC ligand. *Nature* 436, 578–582. © 2005 Nature Publishing Group.

of TCR:p-MHC interactions failed to predict functional ranking of ligand potency.

How to Account for Specificity and Sensitivity of TCR Responses?

The TCR signaling code has to account for the specificity and sensitivity of T cell responses. The kinetic model of T cell activation does not fully account for these two properties since the half-lives of the TCRs for their full agonist, partial agonist, and antagonist p-MHC ligands are relatively similar (Figure 5). Small differences in half-lives yet translate into very different biological outcomes and raise the question as to how T cells discriminate between such similar ligands.

The specificity of T cell responses can be explained by the amplification of small kinetic differences by the TCR signalingome. This amplification results from the existence of multiple sequential biochemical steps in the signaling cascade. One example is the exclusion of molecules with large ectodomains like CD45 phosphatases from the synaptic contact between cells. If the interaction is not long enough, the exclusion of phosphatases is not efficient, which leads to the rapid reversion of proximal biochemical events to the basal state via dephosphorylation. This mechanism describes a variation of the kinetic model of T cell activation, called kinetic-segregation model (Figure 7) and illustrates the multiple cycles of molecular association–dissociation, phosphorylation–dephosphorylation which occur at each step of the TCR signaling cascade. These cycles are coupled to energy-consuming reactions and associated with a waiting time before the completion of these biochemical reactions leads to a productive

signal. By increasing the discrimination potential of T cells for thermodynamically similar p-MHC ligands, these linear amplification steps constitute the basis of the kinetic-proof-reading model of T cell activation (Mckeithan, 1995).

In addition to this linear amplification mechanism, the feedback control model of T cell activation proposes that the $t_{1/2}$ of the TCR:p-MHC interaction also dictates the initiation of nonlinear signaling pathways (Chan *et al.*, 2004). Accordingly, this nonlinear property of TCR signaling networks which magnifies small initial differences during signal propagation was recently observed using mass cytometry, a high-dimensional technique that can probe multiple signaling nodes at the single-cell level (Mingueneau *et al.*, 2014). One example of such nonlinear mechanisms is the negative regulatory loop exerted by the phosphatase SH2-containing phosphatase 1 (SHP-1) on the activity of the SRC kinase lymphocyte-specific protein tyrosine kinase (LCK) (Altan-Bonnet and Germain, 2005). This regulation increases the cell activation threshold and reduces nonspecific LCK activation events. In contrast, only activating ligands induce the phosphorylation of LCK on Ser59 by extracellular signal regulated kinases (ERK), an event which prevents its association with SHP-1. The deactivation of this negative regulatory loop positively reinforces biochemical activities along the whole TCR signaling cascade. Therefore, these nonlinear signaling events increase the signal-to-noise ratio within the TCR signaling network and enhance the ligand discrimination potential of T cells.

If the above models account for the specificity of T cell responses, they fail to explain the sensitivity of T cells to low-abundance ligands. By introducing temporal delays within the signaling cascade, these models actually limit ligand screening capabilities, and thus T cell sensitivity. The serial triggering model of T cell activation accounts for this property by taking into account the relative $t_{1/2}$ of the ternary p-MHC:TCR complexes – in the range of a few seconds (Figure 5) – relatively to the $t_{1/2}$ of p-MHC ligands – in the range of hours (Valitutti *et al.*, 1995). Based on this difference in half-lives, this model proposes that a single activating p-MHC serially engages multiple TCRs. This model explains well why two to three p-MHC complexes are sufficient to trigger T cell activation (Boniface *et al.*, 1998; Cochran *et al.*, 2000), and why even one single p-MHC can induce ZAP70 recruitment and cytokine secretion by promoting TCR clustering (Huang *et al.*, 2013).

Altogether, the kinetic-proofreading, feedback control, and serial triggering models of T cell activation illustrate different mechanisms at play within the TCR signalosome and help explain the existence of an optimal dwell time for the TCR:p-MHC interaction (Figure 5). This optimal dwell time likely reflects a compromise between: (1) a $t_{1/2}$ which is long enough to trigger the linear and nonlinear biochemical events ensuring specific responses; and (2) a dissociation constant which is fast enough to allow for serial triggering of multiple receptors, and thus ensuring high sensitivity of T cell responses.

The Conformational Model of T Cell Activation

Even though kinetic models of T cell activation account for the biological properties of a large number of TCR:p-MHC complexes, there are some thermodynamic exceptions for which

Figure 8 The conformational model of T cell activation. In this model, p-MHC binding triggers a conformational change of the TCR (black arrow). This structural modification would lead to an increased accessibility of the ITAMs to kinases (red arrow). Adapted with permission from Choudhuri, K., Van Der Merwe, P.A., 2007. Molecular mechanisms involved in T cell receptor triggering. *Seminars in Immunology* 19, 255–261. © 2007 Elsevier.

no correlation is observed between the K_D of the interaction and the biological outcome (Yoon *et al.*, 1994; Al-Ramadi *et al.*, 1995). Based on these observations, Janeway (1995) proposed a conformational model of T cell activation almost 20 years ago (Figure 8). Since then, different variations of this model have been proposed, involving rotation, piston-like movements, or deformation mechanisms driven by the forces associated with the binding or detachment of the p-MHC (reviewed in van der Merwe and Dushek, 2011).

3D structures of $\alpha\beta$ TCRs in complex or not with their cognate p-MHC ligands did not show evidence of conformational changes upon ligand binding, except at the TCR:p-MHC interface (Rudolph *et al.*, 2006). One single study identified a conformational change in a domain of the TCR α chain which was later proposed to play a role in TCR oligomerization (Beddoe *et al.*, 2009; Kuhns *et al.*, 2010). These results open the possibility that both conformational changes and receptor clustering participate to TCR signal transduction, similarly to the EGF receptor (Figure 1). However, this model remains to be validated. Conformational change models may also incorporate physical force as one of the actuators of conformational change (Kim *et al.*, 2009).

Additional arguments have been proposed in support of the conformational model of T cell activation. In particular, Aivazian and Stern (2000) proposed that CD3 ζ cytoplasmic domain adopts a folded structure in presence of acidic phospholipids which is refractory to phosphorylation. Building on this observation, other groups proposed that the ITAM motifs are sequestered within the lipid bilayer in steady-state and that TCR triggering makes them accessible to tyrosine phosphorylation (Risueno *et al.*, 2008b; Xu *et al.*, 2008; Figure 9). Yet, these results were later challenged (Fernandes *et al.*, 2010) by the result that mutation of the acidic lipid-binding, basic sequences in CD3 had no effect on proximal TCR signaling (Deford-Watts *et al.*, 2009, 2011). Similarly, a proline-rich sequence within the cytoplasmic tail of CD3 ϵ was initially proposed to be inducibly exposed upon TCR

Figure 9 Sequestration of CD3 ϵ and CD3 ζ ITAMs within the plasma membrane and inducible exposure upon TCR triggering. In this model, basic residues in CD3 ϵ and CD3 ζ (blue dots) interact with the acidic inner leaflet of the plasma membrane, while the phenyl rings of the ITAMs are buried in the bilayer. Ligand binding exposes CD3 cytoplasmic domains. Adapted with permission from Kuhns, M.S., Davis, M.M., 2008. The safety on the TCR trigger. Cell 135, 594–596. © 2008 Elsevier.

triggering, prior to ITAM phosphorylation (Gil *et al.*, 2002). This observation led to a series of follow-up reports (reviewed in Risueno *et al.* (2008a)), but the targeted mutation of this sequence in mice showed that it is largely dispensable for T cell activation (Mingueneau *et al.*, 2008; Borroto *et al.*, 2014).

In conclusion, even if it is not excluded that conformational changes participate to TCR signaling, available evidence for such mechanism remains so far elusive. Recently, the artificial reconstitution of the TCR signalosome into a non-immune cell type showed that TCR triggering could be recapitulated using various engineered receptor–ligand pairs in place of the TCR:p-MHC complex, thus suggesting that conformational changes might not constitute the fundamental mechanism of T cell activation (James and Vale, 2012).

Biochemical Modules and Assembly of the TCR Signalosome

The TCR signalosome can be described by a series of biochemical modules, which initiate the biochemical cascade, amplify, and diversify the initial signal into a complex, multifunctional assembly of proteins with diverse enzymatic and adaptor activities (Figure 10).

Signal Initiation Module

The first detectable biochemical event following p-MHC binding by the TCR is the activation of co-receptor associated tyrosine kinases of the SRC family. In T cells, LCK is the major SRC kinase positively regulating T cell activation and its regulation relies on the existence of two kinase conformations (reviewed in Boggon and Eck, 2004; Salmond *et al.*, 2009; Figure 11). The open conformation of the kinase is the major form of LCK found in T cells in steady-state conditions. Upon TCR triggering, CD4 or CD8 co-receptors interact with the MHC molecule bound by the TCR. Since the affinity of the co-receptor for the MHC is significantly lower than the affinity of

the TCR for the p-MHC ($K_D > 200\mu\text{M}$), the role of the co-receptor is mainly to co-localize LCK in the proximity of the ITAMs and, to a much lesser extent, to stabilize the TCR:p-MHC interaction. Once fully activated by *trans*-phosphorylation of the Y394, LCK dissociates from CD4 and catalyzes the transfer of phosphate groups from adenosine triphosphate (ATP) to the hydroxyl residues of CD3 ITAM tyrosines.

SRC kinase activation leads to full or partial phosphorylation of the 10 ITAMs from the CD3 complex. The main downstream signaling node is the SYK-family kinase ZAP70. Unlike SRC kinases, the primary event driving ZAP70 activation is not the dephosphorylation of an inhibitory tyrosine, but a conformational change occurring upon binding of ZAP70 SH2 domains onto a doubly phosphorylated ITAM motif (reviewed in Wang *et al.*, 2010; Figure 12). The resulting flexibility in the kinase domain facilitates the phosphorylation of several tyrosine residues, which leads to full activation.

Signal Amplification and Diversification Module

The main substrate of ZAP70 is the transmembrane adaptor LAT (Linker for Activation of T cells) (reviewed in Roncagalli *et al.*, 2010; Malissen *et al.*, 2014). The key role of LAT in the TCR signalosome was clearly demonstrated in *Lat*-deficient Jurkat cells, which show almost completely abrogated signaling events downstream of the TCR (Finco *et al.*, 1998), and in *Lat*-deficient mice (Sommers *et al.*, 2005), in which T cell development is arrested at an early stage in the thymus. LAT counts nine tyrosine residues in its cytoplasmic tail. Knock-in mice in which the last four C-terminal tyrosines are mutated to phenylalanine display a phenotype that recapitulates the phenotype seen in *Lat*-knockout mice (Sommers *et al.*, 2001). Therefore, most LAT signaling functions are funneled through phosphorylation of these four tyrosine residues.

Once phosphorylated, LAT recruits cytosolic adaptors including SH2 domain-containing leukocyte phosphoprotein of 76 kDa (SLP76), growth factor receptor-bound protein 2 (GRB2), GRB2-related adaptor protein (GRAP2), as well as enzymes like PhosphoLipase C (PLC γ 1) and IL-2 inducible T

Figure 10 Modular organization of the TCR signalosome. The signal initiation module converts the kinetic properties of the p-MHC ligand into an intracellular biochemical signal, i.e., various levels of CD3 ITAM phosphorylation. This module involves the SRC kinase LCK and the SYK-family kinase ZAP70. The amplification and diversification module recruits multifunctional protein complexes nucleated around the adaptor molecules LAT and SLP76. See text for details. Tailoring T-cell receptor signals by proximal negative feedback mechanisms. *Nature Reviews Immunology* 8, 699–712. © 2008 Nature Publishing Group.

Figure 11 Mechanistic of LCK activation. In its closed conformation, the C-terminal Y505 residue is phosphorylated by CSK and forms an intramolecular interaction with the SH2 domain. The dephosphorylation of this residue by CD45 leads to an open conformation. In T cells, 80% of LCK kinases are in this primed conformation, likely due to the abundance of CD45 on the cell surface. Full activation of the kinase requires the additional *trans*-phosphorylation of the activation loop (Y394). Adapted with permission from Acuto, O., Bartolo, V.D., Michel, F., *et al.*, 2008. Tailoring T-cell receptor signals by proximal negative feedback mechanisms. *Nature Reviews Immunology* 8, 699–712. © 2008 Nature Publishing Group.

cell kinase (ITK). The formation of this multifunctional complex is a highly cooperative process involving protein–protein interactions, phosphorylation events, and other enzymatic activities (Figure 13).

Affinity purification coupled to mass spectrometry recently identified 90 interacting partners in the ZAP70-LAT-SLP76 signalosome, most of which were previously unknown (Roncagalli *et al.*, 2014), thus redefining the breadth of the

Figure 12 ZAP70 activation requires conformational changes and phosphorylation events. Prior to ITAM-binding, ZAP-70 is in an inactive conformation due to hydrophobic interactions between the SH2-kinase inter-domain, the kinase domain, and the SH2-SH2 inter-domain. Binding to a doubly phosphorylated ITAM induces a conformational change, which releases the tandem-SH2 domains from the kinase domain and allows for LCK-mediated phosphorylation of Y315 and Y319, as well as Y492 and Y493 residues in the activation loop. These phosphorylation events lead to maximal activation of the kinase. Adapted with permission from Deindl, S., Kadlecsek, T.A., Brdicka, T., *et al.*, 2007. Structural basis for the inhibition of tyrosine kinase activity of ZAP-70. *Cell* 129, 735–746. © 2007 Elsevier.

Figure 13 The transmembrane adaptor LAT is a key molecular platform nucleating the assembly of a multifunctional protein complex. The four more distal tyrosines of LAT are numbered. Phosphorylated Y#6 recruits PLC γ 1, whereas GRAP2/GRB2-related adaptor downstream of SHC (GADS) binds LAT on phosphorylated Y#7 and Y#8. The cytosolic adaptor SLP76 binds LAT via its association to GRAP2/GADS and PLC γ 1. SLP76 phosphorylation by ZAP70 leads to the recruitment of the TEC-family tyrosine kinase ITK, which can then phosphorylate PLC γ 1 and enhance its activity. The resulting increase in inositol triphosphate (IP3) and di-acyl glycerol (DAG) triggers calcium-dependent signaling pathways, including nuclear factor of activated T cells (NFAT) nuclear translocation, and protein kinase C-nuclear factor kappa B (PKC-NF κ B)/mitogen-activated protein kinase (MAPK) signaling pathways. Phosphorylated SLP76 also recruits VAV, non-catalytic region of tyrosine kinase adapter protein (NCK), Wiskott–Aldrich syndrome protein (WASP), and adhesion and degranulation promoting adaptor (ADAP) which participate to the remodeling of the actin cytoskeleton and cellular adhesion. The adaptor GRB2 can bind several tyrosines of LAT and recruits the guanine exchange factor 'son of sevenless' (SOS) to promote MAPK signaling. The p85A regulatory subunit of the phosphatidylinositol 3-kinase (PI3K) is also recruited by LAT and leads to the formation of the second messenger phosphatidyl 3,4,5-triphosphate (PIP3), which recruits molecules with pleckstrin homology (PH) domains, among which are ITK and protein kinase B (PKB)/AKT. Adapted with permission from Roncagalli, R., Mingueau, M., Gregoire, C., *et al.*, 2010. LAT signaling pathology: An 'autoimmune' condition without T cell self-reactivity. *Trends in Immunology* 31, 253–259. © 2010 Elsevier.

unknown within the TCR signalosome. Also adding to this complexity is the recent observation that LAT adaptors can form protein islands on the cell surface, or, in an alternative model, accumulate within sub-synaptic compartments where

they would participate to TCR signaling (reviewed in [Dustin and Depoil, 2011](#)). The functional importance of these sub-cellular compartments during TCR triggering remains to be understood.

Figure 14 Negative feedback loop operated by the kinase HPK1. HPK1 is phosphorylated upon TCR activation (1), and inducibly recruited on the LAT signalosome by SLP76 (2). HPK1 then phosphorylates SLP76 on the S376 residue which recruits 14-3-3-family molecules (3), leading to the negative regulation of the signalosome (4). S376 phosphorylation peaks between 10 and 15 min after the initiation of TCR signaling. This regulation is thus relatively delayed compared with more proximal feedback loops mediated by SHP1, CD45, or CSK. Adapted with permission from Acuto, O., Bartolo, V.D., Michel, F., *et al.*, 2008. Tailoring T-cell receptor signals by proximal negative feedback mechanisms. *Nature Reviews Immunology* 8, 699–712. © 2008 Nature Publishing Group.

Negative Regulation Modules

In addition to positively regulating signaling, the TCR signalosome also turns on negative regulation loops to keep in check cellular responses (reviewed in Acuto *et al.*, 2008). The existence of such negative regulation modules is clearly demonstrated by the genetic ablation of LAT in peripheral T cells, which leads to hyperactivated and hyperproliferative T cells (Mingueneau *et al.*, 2009; Shen *et al.*, 2010). The TCR-LAT signaling axis is thus more than a positive regulator of TCR signaling.

These negative loops act at different levels of the TCR signaling cascade. Some feedback loops involve kinases, like the Ser/Thr kinase hematopoietic progenitor kinase 1 (HPK1). In its absence, an increased phosphorylation of zeta-associated protein 70 (ZAP-70), SLP-76, PLCγ1, LAT, VAV-1, and ERK kinases is observed. The mechanism of action of HPK1 involves 14-3-3 proteins which negatively regulate TCR signaling by ubiquitination and degradation (Wang *et al.*, 2012; Figure 14).

Phosphatases also mediate negative regulatory events. For instance, CD45 is not only involved in the priming of LCK by dephosphorylating its inhibitory Y505 residue, but also in the downregulation of TCR signaling by dephosphorylating the Y384 residue of LCK as well as tyrosines of the ITAMs. The phosphatase SHP1 also plays a key role in the deactivation of proximal signaling pathways (reviewed in Lorenz, 2009), as demonstrated by the phenotype of mice expressing loss-of-function mutations in the corresponding gene. These mice indeed develop severe autoimmune conditions associated to the prolonged activation of SRC kinases. In addition to SHP1, other phosphatases like PEST domain-enriched tyrosine phosphatase (PEP) and protein tyrosine phosphatase-PEST participate in negative feedback loops through their recruitment by C-terminal SRC kinase (CSK). Both phosphatases dephosphorylate Y394 of LCK. Therefore, the cooperative action of CSK on the inhibitory Y505 residue and of CSK-associated phosphatases on the activating Y394 residue likely explains the tight regulation of LCK activity upon TCR triggering.

Multiple other mechanisms participate to the regulation of the TCR signalosome. These include TCR internalization and degradation (reviewed in Balagopalan *et al.*, 2009), c-casitas B lymphoma (CBL) and CBL-B-dependent ubiquitination and degradation of TCR signaling nodes (reviewed in Mohapatra *et al.*, 2013), lipid phosphatases and kinases (reviewed in Huang and Sauer, 2010), as well as regulations mediated by co-inhibitory receptors that often recruit phosphatases SHP-1 or SHP-2 (reviewed in Chen and Flies, 2013). Altogether, these mechanisms tightly control T cell activation responses and avoid chronic or exacerbated T cell responses. Although these control mechanisms are usually effective, there is a significant burden of autoimmune diseases, which impact a few percent of the world population and allergies to harmless environmental antigens that are even more common.

Conclusions

- The antigenic receptor expressed by T cells is a multiple-chain receptor with separate ligand recognition and signal transduction subunits. The TCR lacks intrinsic kinase activity and non-covalently associates with the tyrosine kinase LCK and ZAP-70 upon TCR triggering. LCK initiates recruitment of ZAP-70 and the assembly of a multi-functional protein complex, designated as the TCR signalosome.
- A large body of evidence supports the role of receptor/co-receptor clustering during T cell activation, even though it remains to determine if clustering involves monovalent receptor complexes and/or preassembled TCR nanoclusters. Available evidence for conformational changes remains so far elusive.
- The properties of activating TCR ligands impose unique constraints on the mechanism of signal transduction. The TCR signaling code has indeed to account for both the exquisite sensitivity of T cells to rare activating p-MHC ligands and the specificity of their responses, only triggered by foreign p-MHC complexes, and not their structurally similar endogenous p-MHC counterparts. Kinetic-proof-reading and feedback control mechanisms contribute to the specificity of T cell responses. Serial triggering of multiple TCRs by the same activating p-MHC ligand increases the sensitivity of T cells to rare ligands.
- Biochemical events driving the assembly of the TCR signalosome involve the activation of SRC and SYK-family kinases, as well as multiple other enzymatic activities, transmembrane and cytosolic adaptor proteins. LAT and SLP76 are the key adaptors which nucleate the cooperative assembly of large multiprotein complexes that funnel most TCR signaling activity.
- Despite remarkable progress made in our understanding of this signaling system since the identification of TCR proteins in the 1980s (reviewed in Weiss, 2005), recent results indicate that many of the newly identified components of the TCR signalosome are not characterized. In addition, T cell activation changes the expression of more than 2000 genes within 24 h following TCR triggering (Mingueneau *et al.*, 2013). Therefore, understanding how proximal signaling events triggered by the TCR signalosome are spatially and temporally integrated within the cell to induce nuclear programs and functional responses will constitute one of the next challenges. Answering these questions will allow us to draw a more complete and dynamic map of the signaling code used by T cells, and ultimately help us design better therapeutics to achieve selective modulation of T cell responses.

T Follicular Helper Cells

Introduction

After infection or immunization, $CD4^+$ T cells respond by differentiating into different subsets of helper T cells that each has a distinct function. Initially, two types of effector $CD4^+$ T cells were described (Mosmann *et al.*, 1986), T helper (Th) type 1 cells that form during infection by intracellular bacteria or protozoa, and Th type 2 cells that form in response to extracellular parasites. It is now recognized that there are numerous T cell subsets that act to facilitate the clearance of pathogens and generate immunological memory. A common feature of the responses to most pathogens, and vaccination, is the production of antibodies that act to neutralize infectious agents and trigger activation of other immune cells. Thus, antibodies can provide protection against subsequent infection by blocking the ability of pathogens to infect the host. Antibodies can be produced via two different cellular pathways. The first is the short-lived extrafollicular response that produces an initial burst of antibodies rapidly after infection. The extrafollicular response can occur with or without T cell help. The second pathway is the germinal center (GC) response, which produces long-lived plasma cells that secrete antibodies that bind pathogens with high affinity. These GC-derived plasma cells are able to provide prolonged protection against subsequent infection. The formation and function of the GC is absolutely dependent on 'help' from a specialized subset of $CD4^+$ helper T cells known as T follicular helper (Tfh) cells. Within the GC, Tfh cells provide help to GC B cells which is essential for mediating the processes of affinity maturation, driven by somatic hypermutation (SHM) and subsequent selection. Tfh cells are instrumental in selecting the highest-affinity GC B cells for differentiation into long-lived plasma cells or memory B cells, and are therefore critical for the output of the GC response. Consequently, Tfh cells are critical for vaccine-mediated immune responses and have been connected with immune pathology in autoimmune diseases and even cancer (Crotty, 2014). In this article we cover the stages of Tfh cell differentiation, their role in the GC response, and how they have been implicated in health and disease.

T Follicular Helper Cell Differentiation

Initiation of Tfh Development

Tfh cell differentiation is a multistage process that is initiated when naïve $CD4^+$ T cells are activated by antigen-presenting dendritic cells (DCs) in the T zone of secondary lymphoid tissues (Moreau and Bousso, 2014). The interactions between DCs and naïve $CD4^+$ T cells are necessary for T cell activation, and it is during these interactions that DCs provide specific cues to T cells that trigger their differentiation into Tfh cells (Ballesteros-Tato and Randall, 2014). As with all other T cell subsets, the first step in Tfh cell differentiation is for naïve T

cells to be primed, requiring two signals to be delivered in tandem. The first is the presentation of processed antigen peptide fragments to helper T cells on class II Major Histocompatibility Complex (MHCII) molecules by DCs, which are recognized by the T cell receptor (TCR) (Grakoui *et al.*, 1999). The second signal is a co-stimulatory signal that involves ligation of the receptor CD28 on T cells by either of its ligands, CD80 or CD86, expressed by a DC that has received the appropriate 'danger' signals (Sharpe and Freeman, 2002). When co-stimulation occurs in concert with MHCII/TCR ligation, T cells are primed and can undergo further development into specialized helper T cell subsets (Deenick and Ma, 2011; Figure 1). The divergence of activated T cells into different T cell subsets is a process that relies on the integration of multiple signals that culminate in the expression of the transcription factors that drive specific T cell fates.

The transcriptional repressor B cell lymphoma-6 (Bcl-6) is essential for Tfh cell differentiation (Nurieva *et al.*, 2009; Yu *et al.*, 2009; Johnston *et al.*, 2009). The initial induction of Bcl-6 expression in Tfh precursor (pre-Tfh) cells requires signals from multiple cell-surface receptors and cytokines delivered by DCs to pre-Tfh cells. Once expressed in pre-Tfh cells, Bcl-6 is able to suppress the expression or function of transcription factors that promote alternative cell fates, thereby skewing the cell toward a pro-Tfh cell lineage (Johnston *et al.*, 2009; Nurieva *et al.*, 2009; Yu *et al.*, 2009).

One of the key requirements for Bcl-6 expression in pre-Tfh cells is ligation of the inducible co-stimulator (ICOS) by ICOS ligand (ICOSL) on DCs (Simpson *et al.* 2010a,b; Bossaller *et al.* 2006), which activates the phosphatidylinositol-3-kinase (PI3K) pathway to facilitate both Tfh differentiation and the subsequent migration of pre-Tfh cells to the border of the B cell follicle and T cell zone (T:B border) (Simpson *et al.*, 2010a,b; Rolf *et al.*, 2010; Choi *et al.*, 2011). Various cytokines produced by DCs synergize with ICOS signaling to promote Tfh formation. Intriguingly, the pro-Tfh cytokines differ between mice and humans. In mice, interleukin (IL)-6 triggers a signaling cascade that results in the phosphorylation of signal transducer and activator of transcription 3 (STAT3), which promotes Tfh differentiation (Ma *et al.*, 2012). In humans, IL-12, IL-21, IL-23, and transforming growth factor- β (TGF- β) are important mediators of Tfh development (Eto *et al.*, 2011; Choi *et al.*, 2013a,b; Nurieva *et al.*, 2008; Ma *et al.*, 2009; Schmitt *et al.*, 2014). After these cytokines bind their respective receptors on activated human T cells, both STAT3 and STAT4 are activated (Choi *et al.*, 2013a,b; Ma *et al.*, 2012). Activated STAT3 and STAT4 then translocate to the nucleus where they contribute to the induction of Bcl-6 (Choi *et al.*, 2013a,b). STAT3 can promote the production and release of IL-21 creating an autocrine signaling loop to further potentiate Bcl-6 expression and Tfh differentiation (Caprioli *et al.*, 2008).

In addition to stimuli that can induce Tfh differentiation, there are also signals that skew activated T cells away from this cell fate. IL-2 is a potent inhibitor of Tfh differentiation,

Figure 1 T cell priming and activation. Naïve CD4⁺ T cells are primed by DCs in the T zone of secondary lymphoid organs through a multitude of cell-surface interactions and external cytokine signals. Two critical activation signals include antigen presentation through MHCII binding to the TCR, and CD28 ligation by CD80/86. The downstream effects of this co-stimulatory activation are induction of Bcl-6 and Maf expression, both of which are known to be important in the development of the Tfh cell phenotype. ICOS/ICOSL signaling contributes to pre-Tfh cell positioning along the T:B border and is also involved with inducing expression of Bcl-6/Maf through the PI3K signaling pathway. DCs produce a range of cytokines that drive Tfh cell differentiation such as IL-6 (mouse), IL-12 (human), IL-21, IL-23 (human), and IL-27. Cytokine binding triggers STAT3 activation and the subsequent induction of Bcl-6, Maf. Negative regulation of Tfh development may occur through the IL-2/STAT5/Blimp1 axis, which is antagonistic to Bcl-6 activity.

therefore the expression of its receptor on activated T cells and/or the bioavailability of IL-2 can polarize T cell differentiation. When IL-2 binds its receptor it triggers a STAT5-dependent activation of B lymphocyte-induced maturation protein 1 (Blimp-1). Blimp-1 is a negative regulator of Tfh cell differentiation as it acts as a potent repressor of Bcl-6 (Johnston *et al.*, 2009; Pepper *et al.* 2011; Johnston *et al.*, 2012).

While Bcl-6 is critical for pre-Tfh cell development, and is often considered to be the ‘master regulator’ of Tfh cell formation, it is not the only known transcriptional regulator involved in this cell fate. These include Maf, interferon regulatory factor 4 (IRF4), basic leucine zipper transcription factor (Batf), and achaete-scute homologue 2 (Ascl-2), which synergize with Bcl-6 for Tfh formation. Maf is induced by ICOS ligation and is central in supporting Tfh cell differentiation and it also supports IL-21 production by Tfh cells (Bauquet *et al.*, 2009; Vogelzang *et al.*, 2008; Kroenke *et al.*, 2012). IRF4 and Batf are

produced at an early stage of T cell activation and contribute significantly to Tfh cell differentiation by ensuring the expression and function of the pro-Tfh lineage factors Bcl-6 and Maf (Ise *et al.*, 2011; Bollig *et al.*, 2012). More recently, the basic helix-loop-helix transcription factor Ascl-2 has been implicated in the initiation of Tfh development (Liu *et al.*, 2014). Ascl-2, like Bcl-6, can repress the transcription of alternative lineage genes and was suggested to precede Bcl-6 upregulation. However, unlike Bcl-6, which is necessary for Tfh formation, T cells that lack Ascl-2 are still able to become Tfh cells, suggesting redundancy in the transcription factors required for Tfh differentiation (Liu *et al.*, 2014).

After being primed by DCs and initiating pre-Tfh cell differentiation, Tfh-precursors require further rounds of antigen presentation to potentiate full Tfh cell development. Although Bcl-6 is a transcriptional repressor, it functions to increase the expression of molecules that are crucial for Tfh migration to

the T-B border or to the interfollicular zone where they encounter B cells (Kroenke *et al.*, 2012). Interactions between pre-Tfh cells and antigen-activated B cells provide further differentiation signals to secure commitment to the Tfh cell lineage.

Stabilization of Tfh Cell Development

Pre-Tfh cells must initiate further interactions with antigen-presenting cells to complete their differentiation. At this stage in the response the majority of mature DCs have died, while the number of antigen-activated B cells, that can also act as antigen-presenting cells, has greatly increased due to clonal expansion. To interact with B cells, pre-Tfh cells need to localize to distinct regions of the secondary lymphoid tissues where they have access to B cells. The Tfh differentiation program, initiated by Bcl-6 and Ascl-2, endows pre-Tfh cells with a chemokine receptor expression profile that facilitates migration to the T-B border and interfollicular zones, where they are able to encounter B cells. Pre-Tfh cells express C-X-C chemokine receptor type 5 (CXCR5), which promotes migration toward the C-X-C motif chemokine 13 (CXCL13)-rich B cell follicle. In addition, pre-Tfh have downregulated C-C chemokine receptor type 7 (CCR7) and P selectin glycoprotein ligand 1 (PSGL1), both of which promote localization of T cells to the CCL19/21-rich T zone (Breitfeld *et al.*, 2000; Yu *et al.*, 2009). In addition to its role as a pro-Tfh co-stimulatory molecule, ICOS is important for the migration of pre-Tfh cells toward the B cell follicle by engaging ICOSL expressed by bystander B cells that do not present antigen to pre-Tfh cells (Xu *et al.*, 2013). In this way, these bystander B cells help localize Tfh cells to the follicular border where they can engage in interactions with, and provide help to, cognate B cells.

The cognate interactions between pre-Tfh and activated B cells at the edge of the B cell follicle are a bidirectional exchange that is essential for the migration of B cells into the GC and for pre-Tfh cells to complete their development into GC Tfh cells (Okada *et al.*, 2005; Kerfoot *et al.*, 2011). These interactions involve a series of co-stimulatory signals that stabilize Bcl-6 expression in pre-Tfh cells. Although B cells are the major type of antigen-presenting cell at this phase of the immune response, they do not deliver a distinct 'B cell specific' signal for Tfh formation as this can be substituted by other cell types in some circumstances (Deenick *et al.*, 2010). The stability of conjugate formation between pre-Tfh and B cells is critical for the transmission of signals between these cells (Cannons *et al.*, 2011). This cellular adhesion between T and B cells is mediated by the signaling lymphocytic activation molecule (SLAM) family members CD84 and Ly108 that are coupled to intracellular signaling pathways by the SRC homology 2 (SH2) domain of SLAM-associated protein (SAP) (Cannons *et al.*, 2011; Kageyama *et al.*, 2012). In the absence of SAP, pre-Tfh/B cells cannot form stable conjugates and Tfh cells do not form (Qi *et al.*, 2008). This results in impaired GC formation and long-lived antibody production, although the extrafollicular short-lived antibody response is intact (Linterman *et al.*, 2009).

During interactions at the T-B border, T and B cells exchange signals through cell-surface molecules and cytokines

that are important for Tfh cell commitment and B cell development (Figure 2). CD40L expressed on Tfh cells binds to its receptor CD40 on cognate B cells promoting B cell survival, antibody class-switching, and inducing ICOSL and CD80/86 expression on the B cell surface, which in turn provide survival signals to Tfh cells (Liang *et al.*, 2002; Foy *et al.*, 1996; Elgueta *et al.*, 2009; Gigoux *et al.*, 2009; Rolf *et al.*, 2010; Linterman *et al.*, 2014). In addition, Tfh differentiation is also supported by various cytokines. In mice, IL-21 and IL-6 support Tfh differentiation, as does IL-27 in both mice and humans (Nurieva *et al.*, 2007; Batten *et al.*, 2010).

As a result of these interactions at the T-B border, there is a fulfillment of Tfh cell differentiation and sustained Bcl-6 expression. These Tfh cells then enter the GC where they provide survival and differentiation cues to GC B cells, and play a central role in selecting which B cells will exit the GC as long-lived plasma cells or memory B cells.

The GC

After receiving T cell help at the T-B border, activated B cells either commit to the extrafollicular pathway, where they develop into short-lived antibody-producing plasma cells, or enter the follicles, where they initiate GC formation (MacLennan *et al.*, 2003). The B cells which will seed the GC downregulate Epstein-Barr virus-induced G-protein coupled receptor 2 (EBI2), enabling them to migrate into the B cell follicle where they undergo extensive proliferation (Pereira *et al.*, 2009). Following an initial rapid proliferative phase, the GC structure becomes anatomically polarized. Proliferating B cells, called centroblasts, localize to the region of the GC closest to the T cell zone termed the dark zone (DZ). This polarization is facilitated by expression of CXCR4 on the centroblasts enabling chemotaxis toward the CXCL12-rich areas in the DZ (Allen *et al.*, 2004). Adjacent to the DZ, and close to sites of antigen entry into the lymphoid tissue, is the light zone (LZ) that contains a network of follicular dendritic cells (FDCs), the nondividing progeny of centroblasts known as centrocytes, and GC Tfh cells (Allen *et al.*, 2004; Victora *et al.*, 2010). Each zone serves a distinct purpose: B cell proliferation and SHM in the DZ and selection by GC Tfh cells and FDCs in the LZ (Figure 3; Allen *et al.*, 2007).

Within the DZ, B cells divide and mutate their B cell receptor (BCR) genes through the directed process of SHM, which introduces random point mutations into the variable (V) region of immunoglobulin genes in a process mediated by the enzyme activation-induced deaminase (AID) (Noia and Neuberger, 2007). SHM results in the generation of a spectrum of BCRs that vary in antigen affinity. The random nature of the mutations induced by SHM requires that centroblasts undergo a process of selection prior to differentiation into long-lived antibody-secreting plasma cells and memory B cells. Following SHM, centroblasts exit the cell cycle, becoming centrocytes that migrate to the LZ where they scan antigen complexes presented by FDCs (Miller *et al.*, 2002). This serves as an opportunity for GC B cells to test their BCR binding affinity. B cells use their newly mutated BCRs to bind and internalize these antigens, then process and present them on MHCII to GC Tfh cells (Figure 4). Only a small fraction of GC B cells that pass FDC

Figure 2 Interactions at the T:B border. After migration to the T:B border, pre-GC Tfh cells complete their commitment to the Tfh lineage through a series of interactions with cognate B cells. B cells take over the antigen-presenting role of DCs by providing an MHCII/TCR signal. ICOS/ICOSL, CD40/CD40L, and CD28/CD86 interactions provide important developmental cues for both pre-GC Tfh cells and B cells. The duration of cognate interactions is crucial for successful signal transduction and is ensured through SLAM-family/SAP-mediated adhesion and stability.

scanning receive sufficient ‘help’ to survive and go on to form stable interactions with cognate GC Tfh cells (Allen *et al.*, 2007). It is thought that GC Tfh cells recognize the relative amounts of peptide:MHCII on the B cell surface as a proxy for the antigen affinity of a given B cell (Victora *et al.*, 2010; Gitlin *et al.*, 2014). A mutated BCR with greater affinity can acquire and process more of an antigen from FDCs and therefore present more peptide:MHCII to GC Tfh cells, thereby out-competing a B cell with a lower affinity receptor that presents less. Thus, GC B cells with mutated BCRs are subject to a Darwinian-like selection that enriches for a population of B cells with enhanced affinity for antigen (Allen *et al.*, 2007; Tarlinton, 2008). Positively selected B cells can differentiate into antibody secreting plasma cells or memory B cells that are exported from the GC, or they can reenter the DZ for further proliferation and BCR diversification (Victora and Mesin, 2014). In this way, GC B cells can experience reiterative cycling between BCR diversification in the DZ and positive selection in the LZ, yielding increasingly higher-affinity cells (Camacho *et al.*, 1998). Occasionally, SHM can produce BCR variants that lose antigen binding completely or have had their antigen specificity altered to recognize self-antigens. In such instances, these cells do not receive help from GC Tfh cells, undergo

apoptosis and are subsequently cleared from the GC by resident macrophages (Victora *et al.*, 2010). Therefore, help from GC Tfh cells is an important mechanism of peripheral tolerance that, if perturbed, can lead to humoral autoimmunity (Linterman *et al.*, 2009).

GC Tfh cells provide help to GC B cells through a range of cytokines and cell-surface molecules and also maintain the expression of SAP that is essential for adhesion and stable interactions (Qi *et al.*, 2008). The key signals from the GC Tfh cells to B cells include CD40L, IL-21, and IL-4 (Crotty, 2014). In mice, IL-21 is required for optimal Bcl-6 expression in GC B cells, which is the transcription factor essential for maintaining the GC B cell phenotype (Linterman *et al.*, 2010; Zotos *et al.*, 2010). In response to SLAM-mediated signaling, GC Tfh cells express elevated levels of Maf, which promotes both IL-21 and IL-4 production by GC Tfh cells (Yusuf *et al.*, 2010; Bauquet *et al.*, 2009; Kim *et al.*, 1999). The cytokines produced by GC Tfh cells support the expression of the molecular machinery involved with class-switch recombination and SHM in GC B cells that are engaged in conjugates with GC Tfh cells (Reinhardt *et al.*, 2009; Basso *et al.*, 2012; Avery *et al.*, 2008). The dialog between GC Tfh and B cells is bidirectional, as during these interactions B cells also deliver signals to GC

Figure 3 Overview of Tfh cell activation, development, and role in the GC response. After naïve $CD4^{+}$ T cells in the T zone are primed by antigen-presenting DCs, they begin the process of differentiation into pre-Tfh cells. Changes in cell-surface chemokine receptors cause migration of primed T cells to the T:B border where they undertake a series of interactions with cognate B cells culminating in Tfh cell differentiation. After receiving cognate T cell help, B cells migrate to the LZ of the GC and become rapidly dividing centroblasts. These centroblasts undergo SHM of their BCR genes before exiting the cell cycle and migrating from the LZ as nondividing centrocytes that localize to the LZ. The centrocytes then scan FDCs and capture presented antigens, which are then processed into peptide fragments. Next, the centrocytes compete to receive help from GC Tfh cells. Those cells with the greatest antigen-presenting capacity, due to their ability to capture the most antigens from FDCs, outcompete lower affinity B cells for help from GC Tfh cells. In the absence of T cell help, GC B cells undergo apoptosis. Those high-affinity GC B cells that receive T cell help then reenter the LZ where they can undergo expansion and further SHM before being exported as either long-lived, high-affinity plasma cells or memory B cells.

Tfh cells that enhance their survival, such as CD28 stimulation that prevents apoptosis of Tfh cells (Good-Jacobson *et al.*, 2010; Linterman *et al.*, 2014).

In addition to positive regulation, GC Tfh cells can also be recipients of negative regulation in the GC. This control of Tfh cell numbers is likely to be critical for a high-quality GC response. Indiscriminate GC Tfh cell help to GC B cells results in a population of GC B cells that have not increased their affinity for antigen (Victoria *et al.*, 2010). By limiting Tfh numbers relative to the number of B cells, Tfh cell help is restricted to only higher-affinity GC B cells that can outcompete lower affinity cells for Tfh cell help. GC Tfh cells express high levels of programmed cell death 1 (PD-1), a CD28 family co-inhibitory receptor (Haynes *et al.*, 2007) that controls the size of the Tfh cell population (Good-Jacobson *et al.*, 2010; Kawamoto *et al.*, 2012; Qi *et al.*, 2014).

The GC is also subject to negative regulation by a defined subset of Foxp3⁺ T cells within the GC known as follicular

regulatory T (Tfr) cells. These cells have been reported as having an inhibitory role in GC size and output as well as repressing GC Tfh cell numbers (Wollenberg *et al.*, 2011; Chung *et al.*, 2011; Linterman *et al.*, 2011). The precise role of Tfr cells in the GC has yet to be revealed, but it is clear that they are important for controlling the size of the GC response.

After the demise of the GC, Tfh cells are able to become memory cells in both mice and humans (Locci *et al.*, 2013; Choi *et al.*, 2013a,b; Hale *et al.*, 2013). These can be resident in secondary lymphoid tissues or circulate in the blood (Fazilleau *et al.*, 2007). The population of circulating Tfh-like cells is a valuable tool for investigating Tfh cells in humans. Upon restimulation, these memory Tfh cells can engage in cognate interactions with memory B cells and support new GC responses (Hale *et al.*, 2013). This, coupled with the formation of memory B cells from the GC, facilitates the establishment of a rapid GC response following future exposure to the same antigen(s). It is this creation of T and B cell memory that is the

Figure 4 Provision of help to GC B cells by GC Tfh cells. GC B cells present antigen to GC Tfh cells via peptide MHCII interacting with the TCR. During these interactions, T and B cells also exchange signals through ICOS/ICOSL, CD40/CD40L, and CD28/CD80 interactions, which provide maintenance signals for both GC Tfh and GC B cells. The SLAM-family/SAP provides the necessary stability for sufficient duration of contact to elicit successful signals. PD-1/PD-1L interactions deliver an inhibitory signal to prevent GC Tfh cells from becoming excessive in number. IL-4 and IL-21 produced by GC Tfh cells provide support to GC B cells, in part, by IL-21 promoting Bcl-6 expression in B cells.

basis for successful vaccination, and that creates the potential for life-long autoimmunity to arise from the GC if the response goes awry.

Tfh Cells in Health and Disease

Given their central role in the selection of high-affinity B cells in the GC, Tfh cells are required for the generation of long-lived, high-affinity plasma cells that are involved in the protective immunity conferred by vaccination. Indeed, most licensed human vaccines are designed to generate long-term antibody responses that block pathogens from establishing an infection. There is now considerable evidence to identify Tfh cell function as the limiting factor for vaccine-induced antibody production in humans (Pallikkuth *et al.*, 2012; Bentebibel *et al.*, 2013; Duan *et al.*, 2014). Additionally, boosting Tfh function in a mouse malaria model provided a significantly higher antibody response (Butler *et al.*, 2012). Taken together, this evidence indicates that Tfh-boosting approaches could be employed to therapeutically enhance vaccination responses.

Tfh cells have been implicated in a number of autoimmune diseases, particularly those in which autoantibody formation is involved in disease pathogenesis. In mice, it is clear that Tfh cells are able to drive a lupus-like phenotype due to dysregulation of the GC response (Linterman *et al.*, 2009). In humans, an increased frequency of circulating Tfh-like cells has been observed in multiple autoimmune diseases such as systemic lupus erythematosus (Simpson *et al.*, 2010a,b), Sjögren's syndrome (Szabo *et al.*, 2013), and juvenile dermatomyositis (Morita *et al.*, 2011). Moreover, increased frequencies of Tfh-like cells in systemic lupus erythematosus and rheumatoid arthritis patients correlate with greater autoantibody levels and more severe disease profiles (Simpson *et al.*, 2010a,b; He *et al.*, 2013). Together, these and many other studies demonstrate that Tfh cells play a central role in humoral autoimmunity, and represent a potential therapeutic target for treatment of these diseases.

One of the more surprising roles for Tfh cells in recent years is their relevance in some types of cancer. An increased presence of Tfh cells and ectopic B cell follicles near the tumor was found to be a biomarker of greater survival in two independent studies of colorectal and breast cancer (Bindea *et al.*, 2013; Gu-trantien *et al.*, 2013). Although the precise role of Tfh cells in tumor immunity is not known, these studies indicated that IL-21 and CXCR13 may be important potentiators of Tfh cell infiltration and their levels positively correlated with patient survival. How Tfh cells might mediate these protective effects will likely be an exciting research area in the future.

Tfh cells are also central to the production of high-affinity IgA in the gut that controls the homeostasis of the commensal microflora there (Kato *et al.*, 2014). Within the gut, IgA can either form in a T-independent fashion or can arise from GCs within the Peyer's patches and give rise to IgA secreting plasma cells with mutated BCRs. If Tfh cell numbers are not controlled in the gut, then the quality of the IgA response is compromised, leading to dysbiosis of the commensal microbiota (Kawamoto *et al.*, 2014).

With advancing age, there is a steady decline in immune function, leading to increased risk of infection, and consequent

morbidity and mortality associated with infectious disease. Despite the success of vaccination programs in younger individuals, vaccines are rather ineffective in older persons (Goronzy and Weyand, 2013). In mice, a decline in GC size occurs with increasing age, as do antibody titers in humans (Stiasny *et al.*, 2012). It appears that aging of the T cells, rather than B cells, is primarily responsible for GC dysfunction with age (Eaton *et al.*, 2004), suggesting that impaired Tfh formation and/or function with advancing age is probably responsible for this decline. In addition, the aged micro-environment also reduces Tfh cell differentiation, suggesting that both T cell intrinsic and T cell extrinsic factors can alter the Tfh cell population in older individuals (Lefebvre *et al.*, 2012).

It is clear that Tfh cells have multifaceted and varied roles in health and disease. Although there has been a great deal of progress in studying Tfh cell biology, further advances in our knowledge may allow Tfh cell manipulation to enhance protective immunity for vaccines and cancer, and inhibit Tfh cells in autoimmune diseases.

"RAGs are the end-point of the strategies developed through evolution to achieve the anticipatory "Promethean" recognition of all universal molecular forms." – A.A. de Freitas, Tractus Immuno-Logicus

Introduction

How does the organism cope with all the various infectious agents that may attack it during a lifetime? The answer resides in the ability of the B and T lymphocytes of the adaptive arm of the immune system to express a vast enough repertoire of antigen-binding molecules (Immunoglobulin – Ig and T-cell receptor – TCR) that any pathogen will face an immune response. Each Ig or TCR polypeptide consists of a constant region that serves structural, signaling, and effector functions, and a variable region that determines antigen recognition and specificity. Ig can be secreted or expressed as a transmembrane surface receptor on B cells (B-cell receptor – BCR). Ig and TCR are heterodimeric proteins with the Ig composed of dimers of an Ig heavy chain (IgH) combined with either a κ or λ light chain, and the TCR composed of $\alpha\beta$ or $\gamma\delta$ dimers (Figure 1).

In vertebrates, including humans and mice, antigen receptor diversity is generated in immature lymphocytes and depends on a process of somatic DNA rearrangement termed V(D)J recombination, a cut and paste mechanism which shuffles a large array of preexisting variable (V), diversity (D), and joining (J) gene fragments to create functional genes encoding for the variable regions of Ig and TCR proteins. This combinatorial approach generates an almost unlimited repertoire of discrete receptor molecules ($\sim 1 \times 10^7$ – without taking into account junctional diversity)

Figure 1 Structure of the antigen receptors. Protein structure of immunoglobulin/BCR and TCR; each polypeptide consists of a constant region (C) that serves structural, signaling, and effector functions, and a variable region (V) that determines antigen recognition and specificity. Immunoglobulins can be produced as either surface or secreted receptor molecules.

from a relatively modest investment in germline coding capacity (in mammals, a few hundred V segments recombining approximately a hundred D and/or J segments). Mammals have seven distinct genomic loci undergoing somatic recombination in a lineage-, stage-, and allele-specific manner: the *IgH*, light κ (*IgLκ*), and λ (*IgLλ*) chain genes in B lymphocytes; and the *Tcr α*, β , γ , and δ chains in T lymphocytes (Figure 2).

Discrete V, D, and J segments are flanked by recombination signal sequences (RSS) that are recognized by a lymphoid-specific recombinase (also called V(D)J recombinase), which consists of the protein products of the recombination activating genes *Rag1* and *Rag2*. RAG proteins constitute a site-specific endonuclease that introduces DNA double-strand breaks (DSBs) adjacent to RSSs. Cleavage at a pair of RSSs (e.g., one adjacent to a V segment and one adjoining a J segment) generates four broken DNA ends: two covalently sealed (hairpin) coding ends, which terminate in the coding segment, and two blunt signal ends, which terminate in the RSS. These DNA ends activate a general DNA damage response (DDR) and are joined by the ubiquitous non-homologous end-joining (NHEJ) proteins to form a coding joint that encodes the variable portion of the antigen receptor protein and a reciprocal product termed a signal joint that is usually excised from the chromosome. Coding joints are typically imprecise, as the coding-end hairpins undergo processing with gain or loss of nucleotides and, subsequent to this, the lymphoid-specific enzyme, terminal deoxynucleotidyl transferase (TdT), adds non-templated nucleotides. This junctional variability contributes further to antigen receptor diversity and is considered characteristic of repair by NHEJ.

The process of V(D)J rearrangement relies on repeated cleavage and rejoining of chromosomal gene segments before a complete Ig/BCR or TCR molecule can be expressed at the cell surface, thus endangering the integrity of the genome, if not the whole organism. As millions of lymphocytes undergo antigen receptor rearrangement every day, there are many opportunities for genome integrity to be ruptured over the course of an individual's lifetime. It is therefore not surprising that multiple restriction mechanisms, often redundant, have also emerged to carefully control when, where, and how recombination occurs (Table 1).

In this article, we will first present the developmental (lymphocyte differentiation) and epigenetic (locus accessibility and substrate selection) aspects of V(D)J recombination regulation. We will then present recent and earlier work that has shed light on the molecular mechanisms of RAG-mediated V(D)J recombination, with an emphasis on the intricate roles of the recombinase (RAG1 and RAG2), DDR and DNA repair proteins. Finally, we will discuss V(D)J recombination in the context of genome maintenance and malignancies of the immune system.

Figure 2 Structure of the antigen receptor genes. Germline organization of antigen receptor loci; all loci contain V and J segments, linked to a constant region (C). The *IgH* and *Tcr β* and δ loci also comprise D segments between the V's and J's. Number of V, D, and J gene segments is indicated in brackets. Genomic length of each locus in megabases is indicated on the left. Adapted from Johnson, K., Chaumeil, J., Skok, J.A., 2010. Epigenetic regulation of V(D)J recombination. *Essays in Biochemistry* 48, 221–243.

Table 1 Levels of restriction for V(D)J recombination

Restriction	Description
Lineage specificity	T-cell receptors are assembled only in T cells, and Ig assembly is restricted to B cells
Temporal-ordered rearrangement	V(D)J recombination follows a precise order: • Between the loci: in B cells, the <i>IgH</i> locus is rearranged before <i>IgL</i> (κ or λ); in T cells, <i>Tcrβ</i> is rearranged before <i>Tcrα</i> • Within each locus: at the <i>IgH</i> and <i>Tcrβ</i> loci, D to J rearrangement precedes V-to-DJ.
Allelic exclusion	At most loci (<i>IgH</i> , <i>Igκ</i> , <i>Igλ</i> , <i>Tcrβ</i> , and <i>Tcrγ</i>), only one allele can be productively rearranged, ensuring that each lymphocyte expresses one receptor molecule with unique antigen-binding properties
RAG expression	RAG1 and RAG2 are co-expressed only in lymphoid cells and only at specific stages in lymphocyte development. RAG expression is cell cycle regulated, with highest levels in G1
Substrate selection	The <i>Tcr</i> and <i>Ig</i> V, D, and J coding segments are flanked by recombination signal sequences (RSS) that are recognized by the RAG proteins. RSS comprise a heptamer sequence, a nonamer sequence, and an intervening spacer of either 12 (12-RSS) or 23 nucleotides (23-RSS). Efficient recombination is only permitted between paired gene segments flanked by a 12- and a 23-RSS (12/23 rule)
Repair pathway choice	RAG DNA ends are repaired exclusively by the nonhomologous end-joining (NHEJ) pathway, which is mostly operative in G0/G1 stage of the cell cycle, when V(D)J recombination occurs. This restriction is also assured by the RAG proteins themselves, which handoff DNA ends from the post-cleavage complex to the NHEJ machinery

Developmental and Epigenetic Regulation of V(D)J Recombination

In adult mammals, B and T lymphocytes are continuously generated from bone marrow hematopoietic stem cells (HSC). While B lymphocytes develop exclusively in the bone marrow,

T lymphocytes undergo most of their development in the thymus (Figure 3). During lymphopoiesis, multipotent hematopoietic progenitors undergo progressive restriction of lineage potential, resulting in B and T lymphoid lineage commitment (Nutt and Kee, 2007; Singh and Pongubala, 2006). To complete their development, all lymphocytes must

Figure 3 Lymphocyte development and V(D)J recombination. RAG expression and rearrangement of V, D, and J gene segments occur at specific stages of lymphocyte development. During B-cell development (lower panel), the *IgH* locus is rearranged at the pre-pro-B and pro-B cell stage and then the *IgL* (κ or λ) in pre-B cells. During T-cell development (upper panel), the *Tcrβ* and *Tcrγ/δ* loci are rearranged at the DN2 and DN3 stages, before *Tcrα* in DP cells. For both *IgH* and *Tcrβ* loci, D to J rearrangement occurs first and is followed by V to DJ. CLP, Common lymphoid progenitor; DN, CD4⁻ and CD8⁻ double negative; DP, CD4⁺ and CD8⁺ double positive; HSC, hematopoietic stem cell; LMPP, lymphoid primed progenitor; SP, single positive (either CD4⁺ or CD8⁺).

assemble a functional antigen receptor (a BCR or Ig for B lymphocytes and a TCR for T lymphocytes). Therefore, V(D)J recombination represents a defining feature of B- and T-cell development (Figures 1 and 3). Importantly, lineage restriction ensures that, although the recombinase (i.e., the RAG1 and RAG2 proteins) is expressed in both cell lineages, *Tcr* genes fully recombine only in T cells and *Ig* genes only in B cells. Ultimately, each lymphocyte expresses a receptor bearing a unique antigen specificity (i.e., monospecificity), which is achieved by limiting the number of functional Ig or TCR alleles to one per cell, a process known as allelic exclusion.

It is important to note that mature B cells, after being stimulated with a cognate antigen, undergo two additional antigen receptor diversification reactions in secondary peripheral lymphoid organs. These two processes are beyond the scope of this article and will therefore not be detailed here, but briefly, class switch recombination (CSR) and somatic hypermutation (SHM), are initiated by the lymphoid-specific enzyme activation-induced cytidine deaminase (AID). SHM introduces point mutations into *IgH* and *IgL* variable region exons, allowing selection of B cells that produce high-affinity antibodies. CSR exchanges the constant region of the *IgH* chain, thereby producing antibodies with distinct effector classes and functions (Dudley et al., 2005).

Ordered Rearrangement of TCR and BCR Gene Segments

In both B and T-cell lineages, V(D)J recombination occurs in a strict temporally ordered manner, with D to J recombination occurring prior to V to DJ rearrangement (Figure 3). B lymphopoiesis depends on the sequential productive (i.e., in frame and translated into a protein) DNA rearrangement of

the *Ig* heavy (*IgH*) chain locus and the *Ig* light chain loci (*IgLκ* followed by *IgLλ*), and their subsequent expression and assembly into BCRs. Rearrangement of the *IgH* locus involves recombination of *D_H* to *J_H* gene segments in uncommitted common lymphoid progenitors (CLP) and pre-pro-B cells, followed by *V_H* to *DJ_H* gene segments in B-cell lineage committed pro-B cells (Borghesi et al., 2004; Hardy et al., 1991). Productive *V_H*-*D_H*-*J_H* rearrangement leads to the expression of the *IgH* chain and its assembly with the surrogate light chain, comprised of the $\lambda 5$ and *VpreB* proteins, and the signaling subunits *Igα* and *Igβ* to form a pre-BCR (Figure 3). The pre-BCR promotes the expansion of a population of large pre-B cells and serves as a critical checkpoint that ensures the expression of a signaling-competent *IgH* chain before rearrangement of the *IgL* chain V and J gene segments in small resting pre-B cells (Figure 3). Successful *V_L* to *J_L* rearrangement results in the expression of either an *IgLκ* or *IgLλ* chain that pairs with the heavy chain to form a functional Ig (Figures 1 and 3).

T lymphocytes undergo an analogous developmental program to produce TCR $\alpha\beta$ or $\gamma\delta$ thymocytes with the majority of mature T cells expressing a $\alpha\beta$ TCR (~95–99% in mice) (Figure 3; Krangel, 2009; Rothenberg and Taghon, 2005). The *Tcrβ*, γ , and δ loci all recombine in immature T cells that are CD4⁻CD8⁻ double negative (DN), with D to J rearrangement occurring prior to V to DJ rearrangement. Successful recombination of *Tcrγ* and γ loci leads to the expression of a $\gamma\delta$ TCR, whereas successful recombination of *Tcrβ* promotes assembly of a pre-TCR, composed of a TCR β chain paired with an invariant pre-TCR α chain. Pre-TCR signaling induces several rounds of proliferation and differentiation of $\alpha\beta$ -lineage cells to the CD4⁺CD8⁺ double positive (DP) cell stage, during

which the *Tcr α* locus is rearranged (Figure 3). At the DP stage, $\alpha\beta$ T cells must successfully undergo positive and negative selection before they can leave the thymus. $\alpha\beta$ TCRs able to bind major histocompatibility complex (MHC) class I or II molecules with at least a weak affinity will provide survival signals to the cell (positive selection) while $\alpha\beta$ TCRs that bind with high affinity to self peptides and/or MHC molecules will provide apoptotic signals to the cell (negative selection). Positively selected $\alpha\beta$ TCR⁺ T cells will exit the thymus as mature single positive (SP) CD4⁺ or CD8⁺ T cells (Figure 3).

Expression of the V(D)J Recombinase

Transcriptional control

RAG expression is restricted to B and T lymphocytes although a small fraction of early hematopoietic progenitors express RAG mRNA (Mansson *et al.*, 2007; Igarashi *et al.*, 2002). In both lymphoid lineages, RAG expression occurs in two waves that correlate with the ordered rearrangement of antigen receptor loci (Figure 3). The first wave results in the assembly of the *IgH* or *Tcr β* chain genes, in pro-B or pro-(DN3) T cells, respectively. Subsequently, the expression of a pre-BCR or a pre-TCR at the cell surface induces a proliferative burst that is associated with the downregulation of RAG expression in cycling large pre-B and pre-(DN4) T cells. Pre-B and DN4 T cells then exit the cell cycle and activate a second wave of RAG

expression leading to the assembly of *IgL* or *Tcr α* chain genes, respectively (Kuo and Schlissel, 2009; Hillion *et al.*, 2009; Figure 3). Importantly, regulation of proliferation versus RAG reexpression and light chain assembly seems to involve a complex interplay between cytokine receptor and pre-BCR or pre-TCR signaling pathways (Clark *et al.*, 2014). Immature pre-B cells continue to transcribe the *Rag* genes if they express a nonfunctional or an autoreactive antigen receptor leading to receptor editing (Figure 4 and below). Immature DP T cells continue to express RAGs and rearrange the *Tcr α* locus until they undergo positive selection and transit to the SP stage.

Many of the transcription factors initiating commitment to the B and T-cell lineages have also been implicated in the regulation of *Rag* transcription, including, for example, E2A, Ikaros, Pax5, Foxp1, FoxO1, and NF- κ B in B cells. It is thought that the aforementioned transcription factors regulate RAG expression by binding to the RAG1 and RAG2 promoters and/or other *Rag* regulatory elements. Interestingly, deletion of certain *cis*-regulatory elements leads to different RAG expression levels in T and B cells, suggesting that each cell type regulates the *Rag* locus using different transcription factors and *cis*-regulatory elements (Kuo and Schlissel, 2009).

Posttranscriptional control

An additional level of regulation of the V(D)J recombinase is at the level of protein stability (Desiderio, 2010). In dividing

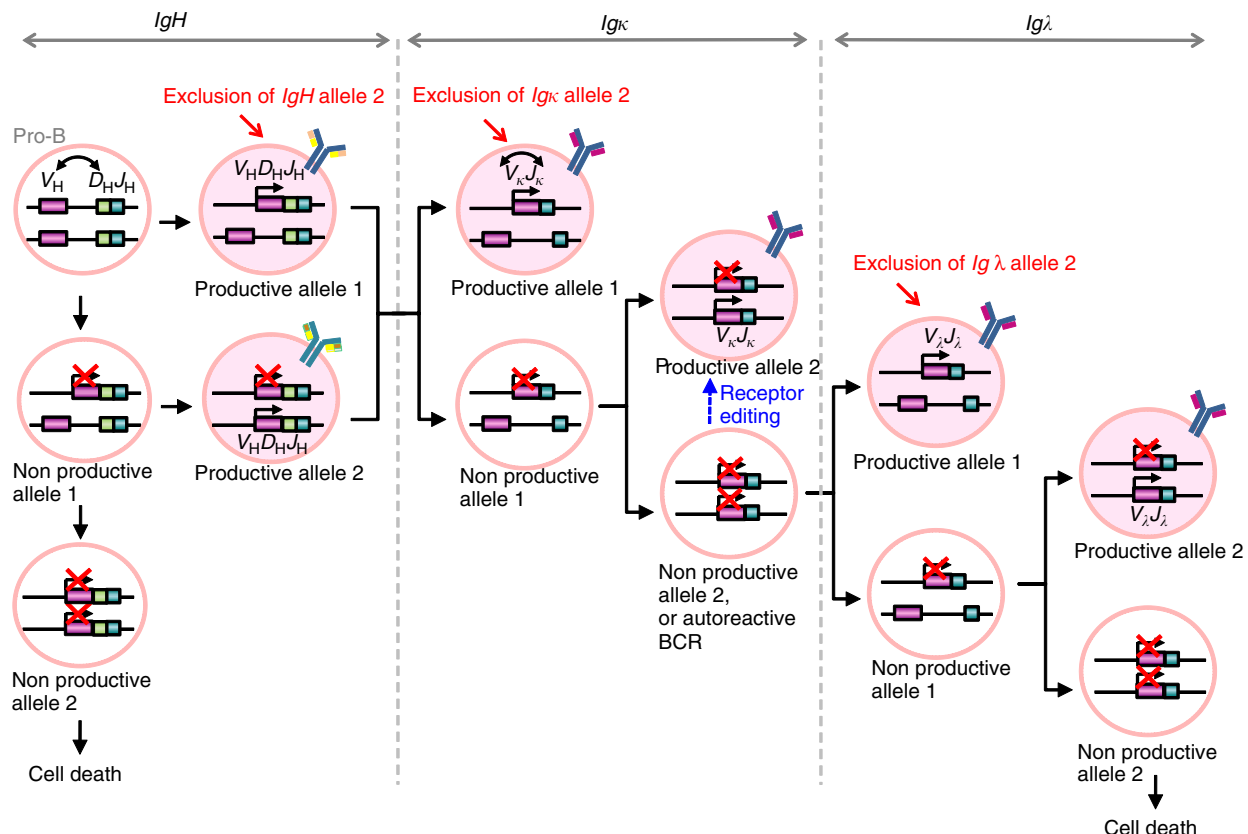

Figure 4 Allelic exclusion and V(D)J recombination. During B-cell development, D_H - J_H rearrangement occurs on both alleles while V_H - D_H - J_H , V_K - J_K , and V_L - J_L are subjected to allelic exclusion. Receptor editing can replace nonproductive or autoreactive V_K - J_K exons by reassembling upstream V_K segments with downstream J_K segments to create a different BCR. If this fails, the *IgL* is targeted for recombination.

cells, RAG2 is degraded during the G1 to S transition of the cell cycle and accumulates again upon reentry into G1, therefore limiting the RAG enzyme activity to the G0/G1 phases. It was demonstrated that the cell-cycle regulator cyclinA/CDK2, which promotes entry into S phase, phosphorylates RAG2 at residue Threonine 490, leading to association with the Skp2-SCF ubiquitin ligase and subsequent proteasomal degradation. This level of regulation restricts recombination to noncycling cells and might help ensure that RAG-mediated DNA breaks do not interfere with the replication machinery. Thymocytes from mice carrying a RAG2 hypomorphic mutation (T490A) that prevents its degradation during G1-S transition accumulate signal ends in S-G2-M and TCR-associated chromosomal translocations (Zhang *et al.*, 2011). Therefore, segregation of proliferation and V(D)J recombination is a crucial regulatory process to prevent aberrant recombination events and translocations.

Allelic Exclusion

One of the axioms of Burnet's clonal selection theory (1957) states that a B- or T-cell expresses a single 'specificity' of antigen receptor (Jung and Alt, 2004; Pernis *et al.*, 1965), and indeed, allelic exclusion ensures that this is the case (In mice, less than 1% of splenic B cells display allelic inclusion – the expression of two different IgH chains (Barreto and Cumano, 2000)). In B-cell progenitors, D_H–J_H rearrangement of the *IgH* locus occurs on both alleles but successful V_H to D_HJ_H rearrangement on one allele and expression of a pre-BCR prevents a second D_HJ_H allele from undergoing V_H to D_HJ_H recombination (Figure 4). Only in cases where rearrangement of the first *IgH* allele is nonproductive (i.e., out-of-frame rearrangement or expression of a premature stop codon), the second allele is targeted for recombination, which occurs in two-thirds of pro-B cells (Mostoslavsky *et al.*, 2004). Failure to produce a functional rearrangement on both *IgH* alleles leads to cell death (Figure 4). In pre-B cells, the *Igk* locus is rearranged preferentially prior to the *Igl* locus (although this can vary between species) and both loci are subjected to allelic exclusion. If rearrangement of the first *Igk* allele is in-frame, a BCR comprised of the heavy and light chains is expressed at the cell surface and, during a process termed negative selection, is tested for auto-reactivity (i.e., recognizing a self antigen). Autoreactive BCRs may be rescued by further rearrangement, which leads to the recombination of unused V_k and J_k segments and to the expression of a novel, potentially non-autoreactive BCR. This process is termed receptor editing and is a major contributor to the maintenance of B-cell self-tolerance. Of note, only five total J_k segments (Figure 2) are available for recombination, therefore limiting the number of secondary rearrangements that can occur in a single B-cell. In case of nonfunctional rearrangement on both *Igk* alleles, the *Igl* locus is targeted for recombination. Failure to produce non-autoreactive BCRs after both *Igk* and *Igl* ultimately leads to cell death (Figure 4).

Similarly, functional rearrangement of the *Tcrβ* locus in DN3 cells leads to the expression of a pre-TCR and inhibits further *Tcrβ* rearrangement. The *Tcrα* locus is less stringently regulated and can undergo multiple rounds of recombination (Krangel, 2009); rearrangement of V_α and J_α gene segments in DP T cells continues until the production of a TCR that is able

to recognize MHC molecules. Unlike the *Igk* and *Igl* loci, the *Tcrα* locus comprises a large array of J_α and V_α gene segments that enable multiple rounds of rearrangements (Figure 2).

The phenomenon of allelic exclusion implies the existence of mechanisms that control the initiation of V(D)J recombination on one allele only, and the exclusion of the other allele from being accessible to the recombinase. Although the precise chain of events remain unclear, theoretical models, most notably the instructive and stochastic models (not necessarily mutually exclusive), have been proposed to explain allelic exclusion during V(D)J recombination (Vettermann and Schlissel, 2010; Mostoslavsky *et al.*, 2004; Jung and Alt, 2004). Additionally, experimental evidence points to cooperation of multiple mechanisms to regulate the initiation and maintenance of allelic exclusion.

The instructive model refers to labeling of the two alleles with different epigenetic marks, such that only one will be prone or 'primed' to rearrange first. In this model, asynchronous rearrangement of the two alleles might result from the low efficiency of the recombination process due to limitations of chromatin accessibility and consequently of the RAG recombinase to access its target gene segments (see below for molecular details of accessibility).

The stochastic model postulates that the probability of productive rearrangement on both alleles in a single cell is very low. In this model, since no coordination is required between the two alleles, asynchrony of allelic recombination or feedback inhibition mechanisms are not relevant. By taking into account the low probability of rearranging one allele in the correct reading frame that encodes a pairing Ig chain, one can calculate the theoretical upper limit for *IgH* allelic inclusion in newly generated B cells to be approximately 20%. However, as aforementioned, the observed frequencies of *IgH* and *IgL* allelic inclusion among peripheral B cells do not exceed 1%. Clearly, additional mechanisms must exist to prevent bi-allelic Ig rearrangement.

Asynchronous replication timing of Ig alleles, which is established and maintained as an epigenetic mark, might function to provide a single allele accessible for initial rearrangement, a prerequisite for additional feedback regulation of allelic exclusion (Farago *et al.*, 2012; Vettermann and Schlissel, 2010; Mostoslavsky *et al.*, 2001).

One such feedback inhibition comes from the pre-BCR or pre-TCR that provides signals inhibiting further rearrangement of the *IgH* and *Tcrβ* loci. The precise signaling pathways involved in this feedback mechanism remain largely unknown but result in the reduced accessibility of the unrearranged V_H and V_β segments to the RAG recombinase (Vettermann and Schlissel, 2010; Brady *et al.*, 2010).

A more recent feedback inhibition model is based on the observation that the two *IgH* alleles are located in close proximity prior to or during the initiation of V(D)J recombination. In this model, pairing of the two alleles is dependent on the presence of the RAG proteins but independent of DNA cleavage. This physical proximity might help communication in *trans* between the two alleles. In fact, DNA cleavage on one allele promotes repositioning of the second allele to pericentromeric heterochromatin (Figure 5). Nuclear repositioning to a repressive environment is dependent on the C-terminal regulatory domain of RAG2 and

Figure 5 Locus accessibility/conformation and V(D)J recombination. Antigen receptor locus accessibility is a central process governing V(D)J recombination. It is regulated at multiple levels that include sterile transcription, subnuclear localization, and histone modifications. Moreover, locus contraction brings together distant segments, allowing the equal use of the more distal and the proximal V segments. Importantly, these changes in chromatin structure and loci conformation are dynamic/reversible.

the action of the DDR factor ataxia telangiectasia mutated (ATM) (see Section Molecular mechanisms of RAG-mediated V(D)J recombination) and likely limits access of the RAG recombinase to the un-cleaved allele during repair of the first break (Chaumeil and Skok, 2013; Chaumeil *et al.*, 2013a,b; Brandt *et al.*, 2010; Hewitt *et al.*, 2009). This mechanism inhibits bi-allelic cleavage and therefore minimizes the presence of multiple DNA breaks in the cell and the risk of genomic instability. Indeed, mice expressing a truncated version of RAG2 or deficient for ATM display increase frequency of bi-allelic breaks, which might provide a direct mechanism for the generation of Ig- and TCR-associated translocations observed in these animals. Additionally, it was recently shown that ATM-deficient mice harbor increased frequency of lymphocytes expressing IgH, IgL κ or TCR β chains from both alleles, further supporting the role of ATM in enforcing allelic exclusion (Steinel *et al.*, 2013).

Accessibility and Chromosomal Organization

How does the recombinase find its specific target sequences within antigen receptor loci during appropriate developmental windows? In the nucleus, the DNA molecule is packaged into chromatin by histones and other nuclear proteins, generating a

3D structure that can evolve both ways from a closed conformation (heterochromatin) to an open conformation (euchromatin) that is accessible to the enzymatic machineries (Figure 5). Upon B- and T-cell lineage commitment, developmental signals lead to chromatin opening that renders V(D)J gene segments accessible to the RAG recombinase. These epigenetic and structural changes are highly dynamic and regulated at multiple levels that include germline transcription (also called sterile or noncoding transcription), chromatin modifications and remodeling, *trans*-acting factors, and alterations in locus conformation (and many others of which, certainly, remain to be discovered).

Transcription and epigenetic marks

Based on the correlation between transcription and V(D)J recombination, accessibility of particular V, D, and J segments was (correctly) proposed 30 years ago as the basis for developmental stage-, lineage-, and allele-specific regulation of V(D)J recombination (Sleckman and Oltz, 2012; Jung and Alt, 2004; Yancopoulos and Alt, 1985; Table 1). Germline transcripts generated from unrearranged V, D, and J segments have since been described for all Ig and Tcr loci, and their stage- and lineage-specific expression strongly correlates with accessibility of these transcribed elements to the V(D)J

recombinase (Sleckman and Oltz, 2012; Matheson and Corcoran, 2012; Jung and Alt, 2004). Germline transcription also includes antisense intergenic transcription that occurs throughout the *IgH* locus (Matheson and Corcoran, 2012). Though the causal link between germline transcripts and recombination has been debated, targeted deletion of promoters and enhancers that drive germline transcripts abrogate recombination, and inhibiting transcription via the insertion of a transcriptional terminator in the *J α* cluster suppresses V-J rearrangement downstream of the terminator (Abarrategui and Krangel, 2006). Additionally, many features of open chromatin, including DNase I sensitivity, DNA methylation, and histone modifications, are connected to germline transcription and recombination (Jaeger *et al.*, 2013; Sleckman and Oltz, 2012; Cedar and Bergman, 2011; Abarrategui and Krangel, 2009). All of this points to the idea that recombinationally active V(D)J loci are associated with open chromatin, while inactive loci are associated with closed chromatin in non-lymphoid cells or recombinationally inactive lymphocytes. In support of this hypothesis, combined action of the transcriptional machinery with specific chromatin remodelers such as the SWI/SNF complex has been shown to modify nucleosome structure such that RSSs become accessible to the RAG recombinase (Bevington and Boyes, 2013; Osipovich *et al.*, 2007, 2009; Golding *et al.*, 1999; Kwon *et al.*, 1998). Last but not least, a direct link between chromatin, transcription and V(D)J recombination came from the discovery of a non-canonical plant homeodomain (PHD) finger in the C-terminal region of RAG2 (Figure 6). The RAG2 PHD finger specifically recognizes hypermethylated histone H3 at residue K4 (H3K4me3) and is important for efficient V(D)J recombination (Matthews *et al.*, 2007; Liu *et al.*, 2007; West *et al.*, 2005; Elkin *et al.*, 2005; Callebaut and Mornon, 1998). H3K4me3 is

tightly associated with transcriptionally active chromatin and also marks antigen receptor loci undergoing or poised to undergo recombination (Desiderio, 2010). Strikingly, genome wide ChIP-seq analyses indicate that RAG2 recruitment mirrors H3K4me3 footprints, with thousands of binding sites in the genome, in contrast to RAG1 which binds predominantly at conserved RSSs (Schatz and Ji, 2011; Ji *et al.*, 2010). Whether RAG2's ability to read the histone code (Jenuwein and Allis, 2001; Strahl and Allis, 2000) is biologically relevant outside recombination at antigen receptor loci is not known.

Chromosomal organization

In addition to RSS accessibility, nuclear location and structural reorganization of the antigen receptor loci provide another important layer of regulation for proper orchestration of V(D)J recombination. Both the peripheral nuclear lamina and regions of pericentric heterochromatin are associated with gene silencing (Towbin *et al.*, 2013). It has been observed that antigen receptor loci are located in these repressive compartments in non-lymphoid and early hematopoietic progenitors but move to euchromatin regions in lymphocytes undergoing V(D)J recombination (Hewitt *et al.*, 2009; Kosak *et al.*, 2002; Figure 5). Although the mechanisms by which antigen receptor loci associate to these repressive regions remain unknown, nuclear repositioning of the *Ig* and *Tcr* loci to repressive regions has been implicated in the initiation and maintenance of allelic exclusion (Johnson *et al.*, 2010; Hewitt *et al.*, 2009; Skok *et al.*, 2007; Roldan *et al.*, 2005).

Most antigen receptor loci encompass large genomic regions (for example, up to 3.2 Mb for the *Ig κ*), with some V segments located at greater distances than others from the D and J segments (Figure 2). The equal use of distal and proximal V segments is essential to insure a complete

Figure 6 Structure of RAG1 and RAG2 proteins. NBD, nonamer-binding domain; PHD, plant homeodomain; Zn, zing finger domain. See text for details (Adapted from Schatz, D.G., Ji, Y., 2011. Recombination centres and the orchestration of V(D)J recombination. *Nature Reviews Immunology* 11, 251–263.).

diversification of antigen receptors. This implies that a mechanism must exist to physically bring together the most distal V segments to the D/J segments before recombination (Figure 5). Fluorescence *in situ* hybridization experiments using locus-specific DNA probes revealed that the *Ig* and *Tcr* loci undergo reversible contraction, facilitating recombination of the locus at appropriate developmental stage (Skok *et al.*, 2007; Sayegh *et al.*, 2005; Roldan *et al.*, 2005; Fuxa *et al.*, 2004; Kosak *et al.*, 2002). More recently, based on an extended 3D structure and predicted dynamic of the *IgH* locus during B-cell development (Lucas *et al.*, 2014; Jhunjhunwala *et al.*, 2008), a model was proposed in which antigen receptor loci are organized in a dynamic rosette-like structure made of multiple loops that undergo variable compaction (Bossen *et al.*, 2012; Schatz and Ji, 2011; Okada and Comings, 1979). Of note, contraction of the *IgH* locus and rearrangement of the distal V_H genes with proximal D_HJ_H segments require key factors that are also involved in B lineage cell priming and commitment, including Ikaros and Pax5 (Reynaud *et al.*, 2008; Fuxa *et al.*, 2004), in addition to ubiquitous factors such as YY1, CTCF and its cofactor cohesin (Ebert *et al.*, 2013; Chaumeil and Skok, 2012). Recent findings also suggest that sterile transcription within the *Ig* loci might also play an active role in locus conformation and looping (Stubbington and Corcoran, 2013; Verma-Gaur *et al.*, 2012).

Molecular Mechanisms of RAG-Mediated V(D)J Recombination

RAG Proteins: Core and Noncore Regions

The RAG recombinase is the only lymphoid-specific protein complex required for V(D)J recombination (Oettinger *et al.*, 1990; Schatz *et al.*, 1989). The mouse and human *Rag1* and *Rag2* genes lie on chromosome 2 and chromosome 11 respectively, immediately adjacent to one another with the entire open reading frame of each gene contained in a single exon. Full-length murine RAG1 (1040 amino acids) and RAG2 (527 amino acids) are conserved polypeptides with species-specific variations of only 3–10 amino acids (Jones and Simkus, 2009). Briefly, RAG1 possesses site-specific DNA binding activity and catalytic residues. RAG2 has little or no DNA binding activity on its own but is crucial to the reaction as it contains regulatory domains that control DNA cleavage, DNA binding, post-cleavage DNA end stabilization, and DNA repair pathway choice (Figure 6; Schatz and Swanson, 2011; Jones and Simkus, 2009; Gellert, 2002). The RAG1 protein contains a nonamer-binding domain, a central region that is responsible for interactions with the RSS heptamer and RAG2, and an active site for DNA cleavage, which includes three essential acidic amino acids (D600, D708, and E962) that coordinate divalent metal ions and are essential for catalysis. RAG1 also contains two zinc finger regions (Zn) important for homodimerization (ZnA) and interaction with RAG2 (ZnB). Interestingly, ZnA also has ubiquitin ligase activity and interacts with and ubiquitylates histone H3 (Schatz and Swanson, 2011; Jones and Simkus, 2009; Gellert, 2002).

Early mutagenesis studies defined the catalytic core of RAG1 and RAG2 proteins to residues 384–1008 and 1–383,

respectively (Jones and Simkus, 2009; Sadofsky *et al.*, 1993, 1994). More recent work has reduced the minimal region of RAG2 required to support recombination to residues 1–350 (Coussens *et al.*, 2013), coinciding with the end of a region containing six kelch-like motifs predicted to adopt a six-bladed β -propeller-like structure (Callebaut and Mornon, 1998) termed the core domain. This core RAG2 region is essential for DNA cleavage activity, enhances RSS binding and interacts with RAG1. The C-terminal noncore region of RAG2 contains multiple regulatory motifs (Jones and Simkus, 2009): a PHD finger that interacts H3K4me3, a cell cycle regulated protein degradation signal in which the phosphorylation of an essential threonine (T490) signals the periodic destruction of RAG2 at the G1-to-S transition, and a highly conserved acidic 'hinge' region that participates in post-cleavage DNA ends stabilization and DNA repair pathway choice (Coussens *et al.*, 2013) through an unknown mechanism. The C-terminus can also bind to phosphatidylinositol phosphate (PIP) as well as core histones (Jones and Simkus, 2009), but the significance of these interactions remains unclear.

DNA Binding and Cleavage

The *Tcr* and *Ig* V, D, and J segments are flanked by RSS that consist of relatively conserved heptamer and nonamer elements, with respective consensus sequences of CACAGTG and ACAAAAACC, separated by an intervening spacer of either 12 (12-RSS) or 23 (23-RSS) nucleotides (Figures 7 and 8(a)). The cleavage starts with the binding of the RAG proteins to one RSS and the formation of a synapsis in which a partner RSS is captured. HMG1 (high mobility group 1), a nonspecific DNA bending protein, facilitates synapsis formation and subsequent cleavage (Dai *et al.*, 2005; Swanson, 2002; van Gent *et al.*, 1997). After binding, the RAG proteins nick one DNA strand precisely between the RSS heptamer and the coding segment. This generates a free 3'-OH that is used to attack the opposite strand in a *trans*-esterification reaction, forming a DNA DSB (Schatz and Swanson, 2011). This paired cleavage step results in the formation of four broken DNA ends: two covalently sealed (hairpin) coding ends and two blunt (signal end) DNA ends (Schatz and Swanson, 2011; Figure 7).

Regulation of Cleavage – 12/23 Restriction and Beyond

Although nicking has been shown to operate at isolated RSSs (and at RSS-like sequences *in vitro*), it is modulated by a distinct synapsis of a 12-RSS and 23-RSS pair (Schatz and Swanson, 2011). Additionally, efficient DSB formation requires 12/23-RSS pair assembly into a synaptic complex with the RAG proteins. This restriction, referred to as the 12/23 rule, directs recombination between appropriate gene segments within a given locus (Figure 8(b)) and likely participates in limiting DSB formation to pre-identified and preassembled RSS partners, therefore preventing aberrant rearrangements. Various lines of evidence indicate that another level of regulation resides in the biochemistry of the RAG-DNA recombination reaction. Though theoretically 12/23 compatible, the direct joining of some gene segments, for example, the *TcrV β* (23-RSS) and *TcrJ β* (12-RSS) segments rarely occurs

Figure 7 RAG cleavage. After RSS recognition and synapsis, RAG1/2 proteins introduce single-strand nicks precisely between the RSS heptamer and the coding segment. The resulting 3'-OH is used to catalyze a direct *trans*-esterification reaction on the opposite DNA strand, generating a DNA DSB. This results in the formation of paired hairpin (coding end) and blunt (signal end) DNA ends that are held in a RAG PCC. DNA ends are then processed and ligated by the NHEJ pathway to form coding and signal joints.

(Figure 8(c)). This restriction is referred to as 'Beyond 12/23' or 'B12/23' and seems to be enforced by the ability of the RAG proteins to initiate cleavage at certain RSSs within the synaptic complex (Banerjee and Schatz, 2014; Schatz and Swanson, 2011; Tillman *et al.*, 2004).

Joining the Broken DNA Ends

After cleavage, the RAG proteins stay associated with the DNA ends in a post-cleavage complex (PCC), yet providing another layer of regulation to be enforced at the joining step (Figure 8, also see below). It is not known whether the four DNA ends all stay associated in a single complex or whether the two coding ends and two signal ends are maintained separately. The fact that the RAGs bind much more avidly to signal-end pairs than coding-end pairs indicates that RAG-signal end PCCs and RAG-coding end PCCs may have different properties (Hiom and Gellert, 1997; Agrawal and Schatz, 1997), and perhaps reflects the need for coding ends to be accessible for processing before ligation. The ubiquitous NHEJ machinery joins pairs of RSS signal ends and pairs of coding segment ends to form signal and coding joints, respectively (Figures 8 and 9).

The V(D)J recombination reaction therefore provides an inherent chromosomal directionality to the rearrangements that is dependent on relative orientation of participating gene segments and their associated RSSs.

NHEJ pathway

In mammalian cells, three specialized repair systems exist to detect, process, and ligate broken DNA ends (Deriano and Roth, 2013). Homologous recombination (HR) and classical NHEJ (cNHEJ) are the major DSB repair pathways. HR functions in the post-replicative S and G2 phases of the cell cycle and employs a template – the sister chromatid or homolog – to direct repair so that DSBs or even gaps can be repaired seamlessly, without loss of genomic information. As opposed to HR, cNHEJ is active throughout the cell cycle, particularly in G0/G1, and utilizes direct joining which does not require sequence homology although very short sequence homologies of a few nucleotides can appear at the junction and might help to align DNA ends. A third and most recently discovered pathway goes by the name of alternative NHEJ (aNHEJ) and was identified in yeast and mammalian cells as a 'backup' system capable of repairing DSBs in cells genetically deficient

Figure 8 Recognition signal sequences, 12/23 rule and beyond. (a) RSS. The consensus sequences of the heptamer and nonamer are shown with either a 12 base pair (12-RSS) or 23 base pair (23-RSS) intervening spacer. (b and c) Schematics of *IgH* (b) and *Tcrβ* (c) loci depicting the order of V, D, and J gene segments rearrangements. Efficient recombination occurs only between gene segments flanked by a 12- and 23-RSS (12/23 rule). Though theoretically 12/23 compatible, the joining of some gene segments, such as the V_β (23-RSS) and J_β (12-RSS) segments in the *Tcrβ* locus, never occurs (beyond 12/23 rule or B12/23), implying that additional mechanisms regulate RAG-mediated cleavage.

for one (or more) factors critical for cNHEJ. aNHEJ is characterized by excessive deletions and frequent, although not invariable, microhomologies at the repair junctions. It is also much less reliable than cNHEJ, as it commonly leads to loss of genetic information and to chromosome translocations (at least in mice).

DSB repair requires DNA end recognition, processing if needed, and ligation (Deriano and Roth, 2013; Helmink and Sleckman, 2012). For cNHEJ, the Ku70-Ku80 heterodimer (Ku) recognizes DNA ends and the DNA ligase complex XRCC4-Ligase IV joins them (Figure 9). cNHEJ of all types of broken DNA ends depends *ad minima* on these 'core' activities. As RAG-cleaved signal ends are perfect blunt ended cNHEJ substrates, they are usually directly ligated with little or no nucleotide additions or losses. RAG-cleaved coding ends however terminate in hairpins that must be processed before joining. After binding to broken DNA ends, Ku recruits the DNA-dependent protein kinase catalytic subunit (DNA-PKcs) to form the DNA-PK holoenzyme. DNA-PK phosphorylates multiple substrates, promoting synapsis of DNA ends and

facilitating the recruitment of end processing and ligation enzymes. One such enzyme is Artemis, discovered as the gene mutated in certain radiosensitive severe combined immunodeficiency (RS-SCID) patients. The endonuclease activity of Artemis is stimulated by DNA-PK and carries out hairpin opening at coding ends. This hairpin opening is often asymmetric from the apex, leading to the addition of short palindromic nucleotides ('P' nucleotides) at the junction (Helmink and Sleckman, 2012). After hairpin opening, the TdT DNA polymerase proceeds to template-independent nucleotide addition ('N' nucleotides) to 3' DNA ends, which, along with P nucleotides, increase junctional diversity at coding joints (Komori *et al.*, 1993; Gilfillan *et al.*, 1993; Desiderio *et al.*, 1984). TdT is only expressed in developing lymphocytes undergoing V(D)J recombination and adds nucleotides primarily to coding ends and not signal ends. Interestingly, TdT expression is absent during fetal life, which leads to a smaller T- and B-cell antigen receptor repertoire in neonates than in adults (Feeney, 1992a,b; Bogue *et al.*, 1991; Gu *et al.*, 1990). Mice genetically deficient for TdT are less sensitive to

Figure 9 Repair of RAG DNA breaks by the NHEJ pathway: DNA end recognition, processing, and ligation. See text for details.

autoimmune diseases (Robey *et al.*, 2004), indicating that the level of antigen receptor diversification must be tightly controlled (at least during fetal and early life) to avoid the appearance of excessive autoreactive specificities in the antigen receptor repertoire. The final step in the repair of RAG-mediated DNA breaks is joining of the DNA ends by the DNA Ligase IV/XRCC4/Cernunnos-XLF complex (Figure 9).

Genetic ablation of the cNHEJ factors Ku, DNA-PKcs, Artemis, DNA Ligase IV, or XRCC4 in mice prevents the completion of V(D)J recombination, arresting B- and T-cell development at an early stage and leading to SCID phenotype (Deriano and Roth, 2013; Boboila *et al.*, 2012). Therefore, although multiple end-joining pathways exist, V(D)J recombination strictly relies on cNHEJ. This restriction is explained both by the limitation of RAG expression to the G1 phase of the cell cycle and by the ability of the wild type RAG complex to guide DNA ends to the cNHEJ pathway (Table 1 and see Section ‘The RAG recombinase: Domestication of a transposase’).

DDR

DSBs activate ATM kinase-dependent DDR in which ATM phosphorylates numerous substrates that mediate cell-cycle checkpoints, chromatin changes and DNA repair (Ciccio and Elledge, 2010). ATM-dependent p53 phosphorylation mediates G1/S checkpoint that arrest or eliminates cells with unrepaired DSBs. ATM also phosphorylates chromatin- and/or DNA-associated proteins, including H2AX, 53BP1, MDC1, and factors of the MRE11 complex (MRE11, NBS1, and RAD50) that assemble over large DNA regions of the chromatin on both sides of DNA breaks to form so-called nuclear DNA repair foci.

Interestingly, these factors, although present at RAG-mediated DSBs (Chen *et al.*, 2000), seem to have only modest

roles in overall V(D)J recombination. The most striking example is 53BP1, which, through participating in cNHEJ, helps to repair AID-dependent DNA breaks occurring during the process of CSR in mature B cells. Although critical for CSR, loss of 53BP1 has only a very modest impact on lymphocyte development and V(D)J recombination, indicating that 53BP1 functions might be compensated by other accessory proteins during the repair of RAG-DNA breaks (Boboila *et al.*, 2012). A similar situation is observed in the case of XRCC4-like factor (XLF-also called Cernunnos). XLF, the most recently identified cNHEJ factor, was discovered simultaneously from patients that display growth retardation, immunodeficiency, and radiosensitivity (Buck *et al.*, 2006) and by a yeast two-hybrid screen for proteins that interact with XRCC4 (Ahnesorg *et al.*, 2006). XLF-deficient mice, unlike other cNHEJ-deficient mice, are not markedly immunodeficient and pro-B cell lines derived from these animals perform nearly normal V(D)J recombination, leading to the speculation that unknown lymphocyte-specific factors/pathways might compensate for XLF function during V(D)J recombination (Li *et al.*, 2008). The answer came from the analysis of mice with combined deficiencies of DDR (ATM, H2AX, or 53BP1) factors with XLF. In these mice, lymphocyte development is blocked at an early stage due to a significant defect in the repair of RAG-mediated DSBs, indicating that XLF serves more major roles in cNHEJ during V(D)J recombination, which are masked by functional redundancies with the ATM-dependent DDR (Kumar *et al.*, 2014).

Studies in pro-B cell lines demonstrated that in the absence of ATM, while V(D)J recombination is not abrogated, a fraction of RAG-dependent DSBs is released from the PCCs, leading to unrepaired DNA ends that can persist in the cell and engage chromosomal instability, including translocations (Callen *et al.*, 2007; Bredemeyer *et al.*, 2006). These findings indicate that ATM, and likely factors of the ATM-dependent DDR, assist in tethering of the DNA ends in the RAG PCC prior to their ligation, a function that might overlap with XLF (Kumar *et al.*, 2014; Deriano and Roth, 2013; Vera *et al.*, 2012). Recent structural analysis of the XLF–XRCC4 complex supports this assumption; XLF forms with XRCC4 long heterofilaments readily observable by electron microscopy (Andres *et al.*, 2012; Ropars *et al.*, 2011). One possible common function between these filaments and the ATM-DDR might be end-tethering/stabilization of the RAG PCC.

Another example of functional redundancy between cNHEJ and DDR factors comes from the analysis of signal joint formation in DNA-PKcs and ATM-deficient lymphocytes. Recent reports pointed to overlapping functions of DNA-PKcs and ATM, mediated through their kinase activities, in promoting efficient signal joint formation and preventing accumulation of signal ends (Zha *et al.*, 2011; Capud and Sleckman, 2011). In response to DSBs, DNA-PKcs and ATM phosphorylate a large number of shared substrates including chromatin-associated factors, cNHEJ factors and potentially the RAG proteins. It is difficult to attribute the flaws in signal joint formation in this situation to defective tethering. Nevertheless, it is likely that cNHEJ and DDR (and RAG proteins – see below) collaborate in maintaining pairs DNA ends together to facilitate proper repair and minimize aberrant end-joining events (Figure 10).

Figure 10 RAG recombinase, DDR, and DNA repair: cooperation to maintain genome stability during V(D)J recombination. See text for details.

The RAG recombinase: Domestication of a transposase

The structure of the *Rag* genes (i.e., DDE motif in RAG1) and similarities in the reaction chemistry (i.e., *trans*-esterification mechanism) of V(D)J recombination and transposition support the idea that the RAG recombinase derives from a transposable element that entered the genome of a common ancestor of all jawed vertebrates (Litman *et al.*, 2010; Fugmann, 2010). However, transposition, the process of moving genetic information from one position in the host genome into another, is substantially divergent from RAG-mediated V(D)J recombination. In the latter, the RAG complex participates in resealing of DNA breaks through cNHEJ and joins the two signal ends together instead of using them to integrate into a new target location. Interestingly, Transib and Transib-like transposition elements contain a single open reading frame that shares similarities with RAG1 (Fugmann, 2010). RAG2, however, lacks any apparent sequence similarity to any known transposon encoded protein (Fugmann, 2010). It is therefore tempting to speculate that RAG2 might have largely contributed to the evolution of an ancient RAG1 transposase into a domesticated V(D)J recombinase that hands off the DNA ends to the cNHEJ machinery, assuring full diversification of the Ig and TCR repertoires (Figure 9) while preserving the genome and organism integrity (Figure 10 and see below).

During the past 15 years, combination of biochemical, genetic, and *in vivo* studies have shed light on a novel role for

the RAG proteins in the joining step of V(D)J recombination. The discovery of separation of function mutants in RAG1 and RAG2 that are capable of cleavage but exhibit severe joining defects provided the first compelling evidence that the RAG PCC might serve a crucial function in joining both coding and signal ends (Roth, 2003). Additional studies showed that destabilization of the RAG PCC in certain RAG mutants leads to repair by HR and aNHEJ (Coussens *et al.*, 2013; Corneo *et al.*, 2007; Lee *et al.*, 2004). These results led to a model in which the quite stable RAG PCC actively directs DNA ends to the cNHEJ machinery for repair, thus protecting them from error-prone end-joining pathways and aberrant recombination events. This model predicts that removal of such RAG regulatory function would affect genome stability during V(D)J recombination. This is in fact the case; mice harboring certain mutations in the C-terminus of RAG2 display a destabilized RAG-DNA end complex, allow increased aNHEJ accompanied by genomic instability and accelerated lymphomagenesis in the absence of p53, generating tumors bearing a complex landscape of translocations, deletions, inversions, and duplications (Deriano and Roth, 2013; Deriano *et al.*, 2011). Interestingly, the lymphomas and translocations seen in RAG2 mutant/p53 deficient mice closely resemble those of ATM-deficient mice (also see below – V(D)J Recombination and Malignancies of the Immune System), suggesting that a similar DNA end release mechanism underlies genomic instability

and lymphoma genesis in both mouse models (Deriano *et al.*, 2011). These results also revealed a genome guardian role for RAG2 during V(D)J recombination and lymphocyte development.

V(D)J Recombination and Malignancies of the Immune System

V(D)J Recombination-Mediated Genomic Instability and Lymphoid Cancers

Theoretical models

There are at least two general models (Figure 11) to explain aberrant V(D)J recombination events (Brandt and Roth,

2009): (1) cleavage errors in which the RAG proteins recognize one or more cryptic RSSs, or other target sequences, generating a chromosomal translocation (e.g., between an antigen receptor locus and another chromosome at a cryptic RSS – Figure 11(a), left panel) or a chromosomal deletion (e.g., between two cryptic RSSs on the same chromosome – Figure 11(a), right panel); (2) aberrant joining which could result from either release of DNA ends from the protection of the RAG PCC and/or absence of DDR or NHEJ factors, both resulting in an increased susceptibility of the free DNA ends to engage genomic instability (Figure 11(b)).

Body of evidence in humans

During *Tcr* or *Ig* rearrangements, other genetic loci are present in an open chromatin configuration and therefore susceptible

Figure 11 Theoretical models of RAG-mediated oncogenic rearrangements. See text for details.

to the activity of the RAG recombinase thus putting the stability of the genome as a whole at risk. The V(D)J recombinase was first suspected to be involved in human lymphoid neoplasm when observations of translocation breakpoints in certain tumors showed that an antigen receptor locus had been fused with other regions of chromosomal DNA, often placing an oncogene next to a highly expressed antigen receptor gene. Examples of this are the *IgH/MYC* translocation in Burkitt lymphoma and the *IgH/BCL2* translocation in follicular lymphoma (Kuppers and Dalla-Favera, 2001; Tsujimoto *et al.*, 1985; Erikson *et al.*, 1982). Aberrant V(D)J recombination activities have also been implicated in T-cell leukemia and lymphoma (Onozawa and Aplan, 2012; Aifantis *et al.*, 2008). In approximately 35% of T-acute lymphoblastic leukemia (ALL), the *Tcr* loci are involved in translocations that probably occur during T-cell differentiation when V(D)J recombination takes place. In addition to translocations, aberrant V(D)J recombination has been shown to generate oncogenic inducing deletions/fusions such as the classic oncogenic *SIL-TAL1* fusion (interstitial deletions involving pairs of RSS-like motifs also called cryptic RSS) in 25% of pediatric T-ALL (Onozawa and Aplan, 2012). Deletions leading to the activation of Notch1 are frequently mediated by dysfunctional RAG activity in murine T lymphomas, and perhaps in adult T-ALL (Aifantis *et al.*, 2008). Lymphomagenic genome rearrangements attributed to RAG activities are also seen in B-ALL, including *IKZ1* deletions and alterations of, for example, *PAX5* (Mullighan and Downing, 2009; Kuppers, 2005; Kuppers and Dalla-Favera, 2001). These genomic aberrations are normally associated with multiple other chromosomal abnormalities, often concealing the underlying mechanism(s) implicated in the onset and in the progression of the disease. Nevertheless, a recent study clearly points to RAG-mediated recombination as the predominant driver of oncogenic rearrangement in a subtype of ALL (ETV6-RUNX1-positive ALL) (Papaemmanuil *et al.*, 2014). The authors performed genome and exome sequencing on over 50 leukemic samples and resolved 354 genomic structural variations (SVs) at base-pair resolution. Using this data, they searched for typical features of RAG activity and found that RSSs were identified in 12% of the SVs, close to 40% of the breakpoint regions contained cryptic RSSs, and non-templated sequences were found at 70% of the breakpoints. Of note, these motifs were highly enriched compared to genomic data from several solid tumors, which presumably do not originate from RAG-expressing cells. A possible explanation for the increased generation of SVs at RAG target sites could be that in various ALL subtypes, including ETV6-RUNX1-positive ALL, the RAG genes are constitutively expressed. However, in opposition to this idea, in ETV6-RUNX1-positive ALL, RAG-motifs were also enriched compared to the haplodiploid ALL and early T-cell precursor ALL subtypes. These observations suggest that ETV6-RUNX1-positive ALL cells might harbor a unique deregulation of the V(D)J recombinase that drives genomic instability and cell transformation. Additional experimental approaches will likely provide insight into the underlying mechanisms of V(D)J recombinase-induced SVs in cancer genomes.

Experimental evidences

Direct evidence that the RAG recombinase mediates genomic instability *in vivo* comes from the analysis of mice deficient in

factors involved in detecting and responding to DNA breaks (Gostissa *et al.*, 2011; Nussenzweig and Nussenzweig, 2010; Jankovic *et al.*, 2007). The clearest examples come from mice deficient for various cNHEJ factors (Ku80, XRCC4, Ligase IV, DNA-PKcs, or Artemis) that are also deficient for p53 tumor suppressor. These mice invariably develop pro-B cell lymphomas harboring oncogenic translocations that link the *IgH* locus to sequences near *c-myc* on chromosome 15 (or *N-myc* on chromosome 12 in the case of Artemis deficiency), and both genes are commonly amplified. The majority of breakpoints in the *IgH* locus are near the J_H cluster, supporting the idea that failed V(D)J recombination initiates these translocations. Additionally, breeding these mice onto a RAG-deficient background leads to the appearance of B-cell lymphomas that lack these typical translocations and amplicons. Similarly, elimination of RAG in ATM-deficient mice, which routinely develop T-cell lymphomas with recurrent translocations and amplifications involving the *Tcr α / δ* locus on chromosome 14, leads to the kinetically delayed appearance of thymic lymphomas that lack the *Tcr α / δ* translocation. Thus, abundant direct experimental evidence links RAG activity to the generation of recurrent oncogenic translocations (Deriano and Roth, 2013; Gostissa *et al.*, 2011; Nussenzweig and Nussenzweig, 2010; Jankovic *et al.*, 2007; Roth, 2003). These findings also demonstrate that the cNHEJ pathway acts as a genome guardian by promoting faithful joining and that p53 activation protects against RAG-mediated translocations (Deriano and Roth, 2013; Roth and Gellert, 2000).

Although RAG involvement in generating *Ig* or *Tcr* breaks in human and mouse lymphomas has been well characterized, the origin of the DSB on partner chromosomal loci, such as the *BCL2* or *MYC* oncogenes, is more speculative. As aforementioned, the RAG proteins might cleave cryptic RSSs at non-V(D)J loci (Papaemmanuil *et al.*, 2014; Marculescu *et al.*, 2002; Lewis *et al.*, 1997). RAG also recognizes sequences that adopt a non-B DNA structure, as found in the main breakpoint region of *BCL2*, and nicks DNA at sites of transition from double stranded-DNA to single stranded-DNA; such nicks could be converted to DSBs by several mechanisms and are involved in the generation of chromosomal translocations (Raghavan *et al.*, 2004; Lee *et al.*, 2004). Finally, translocations might involve one RAG-mediated DSB and a DSB outside antigen receptor locus generated by other mechanisms (Bunting and Nussenzweig, 2013; Alt *et al.*, 2013). In any case, RAG recombinational activities need to be tightly kept in check to avoid genome scrambling and appearance of potentially oncogenic mutations.

V(D)J Recombination and Immune Deficiency Disorders

As previously mentioned, V(D)J recombination is a prerequisite to lymphocyte differentiation and the generation of a full repertoire of different *Ig* and *TCR* molecules. In humans, naturally occurring gene mutations have been identified that cause a complete or partial loss of physiological V(D)J recombination activity (Woodbine *et al.*, 2014; Schatz and Swanson, 2011; de Villartay, 2009). The most striking examples come from patients deficient in NHEJ proteins, such as Ligase IV, XLF, Artemis, or DNA-PKcs, who typically display radiosensitivity (as a consequence of the role of NHEJ in the

rejoining of radiation-induced DSBs) and severe combined immunodeficiency (RS-SCID). Of note, NHEJ deficiency can also confer additional developmental abnormalities, including microcephaly (Woodbine *et al.*, 2014; de Villartay, 2009). RAG mutations have also been associated with a spectrum of severe immune deficiency disorders. Complete RAG deficiency is associated with classical SCID and absence of T- and B cells. RAG deficiency with residual V(D)J recombinational activity is associated with several clinical and immunological subtypes such as complete or incomplete Omenn syndrome, $\gamma\delta$ T-cell expansion, granuloma formation, and maternofetal engraftment (Schatz and Swanson, 2011; Niehues *et al.*, 2010; Villa *et al.*, 2008).

Acknowledgments

Research in the Deriano lab is supported by the Institut Pasteur, the CNRS, as well as by the European Research Council under the ERC starting grant agreement #310907.

T Cell Memory to Viral Infections

Background

The ability of the immune system to develop long-lived memory is critical for its function. Perhaps the most important development in this respect was the observation by Edward Jenner that exposure to cowpox led to acquired resistance to smallpox, laying the foundations for vaccination. Since that time much has been learned about the mechanisms underlying protective immunologic memory – in other words immunity. Much of the recent drive to understand this in more depth has been the need to develop vaccines against more complex pathogens, especially persistent virus infections such as human immunodeficiency virus (HIV) and hepatitis C virus (HCV). Defining the rules that govern the control of T cell memory populations is a central part of this effort. Although we still lack effective vaccines for HIV and HCV, much has been learned about the nature of T cell responses against such pathogens, as well as those in apparently successful immune responses. These responses will be described in this article, together with discussion of some of the unanswered questions that remain.

Memory Formation

T lymphocytes develop in the thymus, until they are released as mature T cells which circulate in the bloodstream, migrating through successive lymph nodes scanning antigen presenting cells (APCs) within for presentation of their cognate antigen. At this stage of differentiation, until they have encountered antigen, they are described as 'naïve.' Upon recognition of antigen, a specific T cell is activated to undergo clonal expansion and differentiation into a pool of 'effector' cells that perform specialised functions. Classically, these functions have been divided based upon coreceptor expression, with CD8 + T cells differentiating into cytotoxic T lymphocytes (CTLs) with the ability to kill infected cells through the release of cytotoxic molecules such as perforin and granzymes, and CD4 + T cells differentiating into T helper (Th) cells of which there are several lineages, including Th1, Th2, Th17 and T regulatory (Treg) cells. These lineages are defined based upon the predominant cytokines produced and the characteristic transcription factor expression, and are thought to differentially develop according to innate immune cues in the milieu during antigen presentation that communicate the type of infection to which the antigen is associated. For example, the recently identified Th17 lineage is characterized by production of interleukin (IL)-17 and expression of the master transcription factor RAR-related orphan receptor (ROR) γ t, and is thought to develop in the presence of innate cues triggered by extracellular bacterial and fungal infections (Cosmi *et al.*, 2008). IL-17 acts on tissue cells to produce mediators that increase neutrophil recruitment and inflammation – an appropriate response to extracellular pathogens.

Following clonal expansion, and generally after removal of the invading microorganism, T lymphocytes undergo extensive contraction. Numbers of pathogen-reactive cells reduce rapidly due to activation induced cell death (AICD) before reaching a plateau, with a percentage of effector cells remaining at increased numbers compared to their naïve precursors (see Figure 1). This pool of long-lasting antigen-specific T cells form a defining attribute of the adaptive immune system, namely their ability to develop immunological memory. Memory is typically defined by the persistence of increased numbers of antigen-reactive lymphocytes after removal of antigenic stimulation (Lau *et al.*, 1994; Murali-Krishna *et al.*, 1999; Swain, 1999) together with the capacity to expand and differentiate rapidly upon secondary challenge (Lau *et al.*, 1994; Veiga-Fernandes *et al.*, 2000). This definition and analysis becomes more complex in situations where the pathogen may persist – even at relatively low levels or at specific sites.

Phenotypes of Memory T Cells

Human memory T cells can be identified by a switch in isoform from CD45RA to CD45RO, yet with reversion to CD45RA possible, especially in the CD8 + T cell subset. Further phenotypic analysis of human memory cells also revealed a dichotomous heterogeneity based upon expression of the lymph node-homing chemokine receptor CCR7 (Sallusto *et al.*, 1999). Expression of CCR7 by 'central memory' T cells (T_{CM}), together with CD62L, enables them to home to the lymph node where they can proliferate to initiate secondary responses. T_{CM} cells may produce few cytokines except IL-2. On the other hand, CCR7 negative 'effector memory' T cells (T_{EM}) typically produce high levels of several cytokines, including IL-4 and interferon (IFN)- γ and circulate through non-lymphoid tissues. Characterization based upon expression of

Figure 1 Schematic graph representing the different developmental pathways of memory T cells following viral infection.

Figure 2 Flow cytometry plot (left) showing CD8 + T cells divided into memory subsets (right) based upon expression of CCR7 and CD45RA. T_{CM}, central memory; T_{EM}, effector memory; T_{EMRA}, terminally differentiated memory.

both CD45RA and CCR7 divides T cells into three CD4 + subsets (CCR7 + CD45RA + naïve, CCR7 + CD45RA – and CCR7 – CD45RA – memory) and four CD8 + subsets (with an additional CCR7 – CD45RA +), with re-expression of CD45RA associated with terminal differentiation (T_{EMRA}). These subsets are shown in **Figure 2**, although very few T_{CM} CD8 + T cells are present in the circulation.

There has been some discussion regarding the differentiation pathways of these distinct memory subsets. Originally it was thought that activation of naïve T cells generated T_{CM} cells, which then provided a source of T_{EM}, with more immediate effector function (Sallusto *et al.*, 1999; **Figure 3(a)**). Conversely, studies of adoptive transfer with T cell receptor (TCR)-transgenic mice suggested a linear differentiation pathway, from naïve to effector to T_{EM} cell, which may subsequently convert to T_{CM} (Wherry *et al.*, 2003; Bouneaud *et al.*, 2005) (**Figure 3(b)**). Yet, it has been suggested that this conversion from T_{EM} to T_{CM} is an artefact of the TCR-transgenic system, with T_{EM} cells instead representing a stable memory phenotype (Marzo *et al.*, 2005). Still further studies have suggested that the two subsets are in fact distinct and independent (Baron *et al.*, 2003), whereas others suggest that an effector stage may not even be required to generate memory cells (Manjunath *et al.*, 2001; **Figure 3(c)**).

Another key question is whether those cells which develop into memory cells – so called ‘memory precursors’ – can be distinguished from those which will die during the contraction phase. Indeed, expression of the IL-7 receptor (IL-7R) (Kaeche *et al.*, 2003), together with downregulated expression of CD25 (Kalia *et al.*, 2010) and KLRG1 (Sarkar *et al.*, 2008), is thought to distinguish those effector CD8 + T cells which will differentiate into memory cells. These phenotypic changes are accompanied by profound changes within the cell in relation to metabolism, with the switch from acute expansion of effector cells to memory formation being associated with a switch away from the aerobic glycolysis required for rapid proliferation.

Tissue-Resident Memory

In addition to the two T cell memory subsets already described, a population of memory T cells that, unlike T_{EM}, do not recirculate, has been identified in certain peripheral tissues, including the skin, gut, and lung. This population is stably maintained within the respective tissue, independently of their circulating counterparts, and have hence been described as ‘tissue-resident memory’ T cells (T_{RM}). Like innate immune cells, T_{RM} cells reside in tissues that form a barrier to invading pathogens, and can provide potent protection against re-infection (Jiang *et al.*, 2012). Transcriptional studies have demonstrated CD8 + T_{RM} to be distinct from circulating memory CD8 + T cells (Wakim *et al.*, 2012; Mackay *et al.*, 2013), yet few definitive markers of T_{RM} have been identified to date. However, expression of CD103 (integrin α E), which is expressed on memory CD8 + T cells within many tissues yet low on circulating T cells, identifies T_{RM} within human mucosal tissues such as gut and lung (Sathaliyawala *et al.*, 2013), and has hence been used as a marker of T_{RM} cells. CD103 binds E-cadherin, a molecule expressed on epithelial cells, and therefore may function to retain T_{RM} cells within peripheral tissues. However, it should be noted that CD103 has also been described as a marker of regulatory T cells, and therefore it is the combination of CD103 expression together with their tissue localization that identifies T_{RM} cells. In a similar way, CD69 has also been used as a marker of T_{RM} (Sathaliyawala *et al.*, 2013; Turner *et al.*, 2014), but can also be expressed by activated T cells within the circulation. CD69 expression leads to down-regulation of the sphingosine-1 phosphate receptor 1, which mediates egress from tissue to the lymph and blood. The differentiation pathway of this unique T_{RM} population is largely unknown, with questions such as whether there are distinct T_{RM} precursors within the effector cell pool, or whether T_{EM} cells can differentiate into T_{RM} once recruited into tissues remaining to be answered, although it is

Figure 3 Potential pathways of differentiation of memory T cells.

clear that the specific tissue microenvironment plays an important role.

Different Phenotypes Characterize Different Viral Infections

Although the above model of expansion, contraction, and long-lived memory does apply to many viral infections, it is by no means the only pathway of differentiation available to T cells (see Figure 1). Most of the work in this area is based on studies of CD8⁺ T cells. This is partly for technical reasons, since the expansion of these cells following virus infection tends to be very large, and thus the populations are relatively easier to track and characterize. The process of tracking T cells was transformed in the mid-1990s by the introduction of major histocompatibility complex (MHC) peptide tetramer technology. 'Tetramers,' or more generally 'multimers,' are constructs based on soluble MHC-peptide complexes generated *in vitro* according to the antigen of interest. Such soluble complexes can be bound as multimers around fluorescent molecules such as tagged streptavidin, and their avidity is such that they will bind and be internalized by T cells bearing the appropriate TCR for that complex (see Figure 4). This allows the cells to be tracked using flow cytometry, and additionally allows the surface phenotype and intracellular molecules to be readily assessed on the same antigen-specific cell (Altman *et al.*, 1996).

The advent of this technology revealed the diversity of T cells targeting different viruses, especially those with some degree of persistence, such as the herpesvirus group, HIV and HCV. One way of visualizing this diversity is along a spectrum based on antigen re-encounter, maturation, or linear differentiation over time (Appay *et al.*, 2008). In those virus infections where exposure is very limited, the responses contract as above and long-lived memory is maintained in an antigen-independent manner (central memory pools dominating). In settings where antigen exposure is more prolonged, the predominant cell seen tends to acquire 'effector' memory characteristics. This includes loss of lymph node homing molecules such as CCR7 and CD62L, loss of co-stimulator dependence through CD28 and CD27 down-regulation, and acquisition of effector functions through up-regulation of perforin, for example. At one end of this spectrum is Epstein-Barr virus (EBV), which has a relatively limited maturation, while at the other is cytomegalovirus (CMV) in mouse and man, which has the most extreme of the differentiated phenotypes (see 'memory inflation' below).

The idea that these memory pools represent a spectrum has been reinforced recently by the advent of a new technology – cytometry by time of flight (CyTOF) (Newell *et al.*, 2012). This technique is based on the use of antibodies conjugated to metal isotopes, which are bound to the cell surface as in normal fluorescence-based methods. Cells are passed singly into a chamber where they are vaporized and their metal ion cargo released for analysis by mass spectrometry. The resulting

Figure 4 Diagram of MHC molecules complexed around fluorescently-tagged streptavidin to form an MHC class I Tetramer (left) used to identify viral-specific cells by flow cytometry (right).

information allows analysis of multiple antibodies (30–60 in many cases), which can all be independently assessed, overcoming the limitations of fluorescence caused by spectral overlap. By analysis of multiple memory markers, it is clearly shown that T cell memory phenotypes exist as a broad range, or continuum, without a clearly defined barrier between them. Increasing resolution of this type will ultimately allow better description of these memory pools, beyond the somewhat arbitrary markers currently used.

Immune Exhaustion

One further feature of antiviral memory populations, which has emerged from the study of persistent viruses – notably lymphocytic choriomeningitis virus (LCMV) in the mouse – is the phenomenon of ‘exhaustion.’ This is most evident in certain strains of the virus such as LCMV Clone 13 and DOCILE strain, which, when inoculated intravenously at high dose, lead to an overwhelming infection which can persist. This is accompanied by down-regulation of the T cell response to the virus, most dramatically seen as the emergence of CD8⁺ T cell responses that are poorly functional, with up-regulation of multiple inhibitory receptors. Since LCMV itself is non-cytopathic, this down-regulation of T cell reactivity has been rationalized as a mechanism induced to limit immune-mediated pathology. The most well-studied of these inhibitory molecules is programmed death 1 or PD-1. Blockade of PD-1 can relieve the inhibition of CD8⁺ T cells and lead to increased control over the viral load (Barber *et al.*, 2006). Downstream of PD-1, down-regulation of the critical transcription factor T-bet (TBX21) is responsible for loss of many effector functions (Kao *et al.*, 2011).

Immune exhaustion has also been observed in human persistent virus infections such as HIV, HCV, and hepatitis B virus (HBV). In these infections, high levels of PD-1 have been observed on virus-specific T cell populations, as well as other inhibitory receptors such as CD160, Lag-3, and TIM3. This would be consistent with the marked down-regulation of antiviral population size against HCV in chronic infection, compared to maintenance of classic memory populations in the subset of patients who control in-

fection after acute exposure. One further phenomenon serving to limit the efficacy of such antiviral populations is the emergence of T cell escape mutations within the virus (Phillips *et al.*, 1991). Variable viruses, where RNA replication is error-prone and proof-reading is limited, generate multiple mutations which can serve to impair T cell recognition via loss of peptide binding to MHC, lack of processing at the proteasome, or loss of TCR recognition. Under immune selection such variants come to dominate and lead to both loss of immune control and loss of TCR-triggered T cell maturation.

Memory Inflation

At the other end of the spectrum, as mentioned above, persistent infection with CMV in both mouse and man is associated with the development of responses which show markers associated with ‘late’ differentiation. This phenomenon is also associated with numerical expansion of these ‘effector memory’ pools, and accumulation of large antiviral populations in organs such as lung and liver, as well as in blood. In the mouse model, where T cells can be tracked after infection, it is apparent that such populations may not dominate initially, but expand gradually over time, hence the phenomenon has been termed memory ‘inflation’ (O’Hara *et al.*, 2012). The same phenomenon has been observed in responses against other persistent viruses, including viruses such as those of the parvovirus family, without a classic latency program. Interestingly the phenomenon is restricted to limited subsets of T cells responding to epitopes that appear to be presented at sufficient levels during the memory phase. Responses to many other epitopes, including those that elicit dominant responses during acute infection, undergo a classical contraction and generate memory pools indistinguishable from those seen against acute nonpersistent infections. It is believed that these peptides are not presented efficiently during memory formation, either through competition, or due to the requirement for the immunoproteasome for processing, which is restricted to certain cell types under noninflammatory conditions.

Atypical Memory

The ability to track memory populations using MHC-peptide tetramers has revealed some unexpected responses in addition to those described above. The first of these is the identification of T cell responses with apparent memory characteristics in naïve individuals. These have been described in the case of HIV and HCV in humans, and to a range of pathogens in mice. This is thought to be due to the natural cross-reactive capacity of TCRs, which cannot be uniquely specific to a single MHC-peptide complex. In the case of HIV, peptides have been described from the gut microbiome that could act to prime HIV specific T cells in non-HIV exposed individuals. In the case of HCV, a cross-reactive peptide from influenza has been suggested, although the avidity of this interaction is rather lower than that of most conventional TCR-peptides. In both cases, the question of whether such antigen-experienced pools can contribute to protection or immunopathology remains open, but it is certainly clear that such cross-reactivity, or heterologous immunity, even at low level, could serve to mold the TCR pool in unexposed individuals and/or T cell memory after infection (Welsh *et al.*, 2010).

The reverse situation has also been observed. Very sensitive assays can identify naïve precursors in unexposed individuals at extremely low frequencies (around 1 in a million T lymphocytes) (Alanio *et al.*, 2010). Naïve T cell pools can also be identified in some individuals with persistent infections such as HCV. Additionally, there are populations of T cells with 'naïve' markers which can be observed after infection or vaccination (CD45RA⁺, CCR7⁺), which have not been well characterized but clearly are antigen responsive, have expanded in response to antigen and remain functional (Barnes *et al.*, 2012).

One recent surprise in this field is that a substantial proportion of CD8⁺ T cells (about 1 in 6) in human blood do not represent a typical antiviral response, but rather an innate type of lymphocyte termed a mucosal associated invariant T cells or MAIT cell. These T cells possess many markers typical of 'effector' memory pools, and home to organs, especially the liver, where they represent around 50% of the CD8⁺ T cell pool. However, their TCRs are not diverse like conventional T cells, but rather semi-invariant (possessing a restricted Va7.2-Ja33 rearrangement and limited beta chain pairing), and this TCR is bacterially responsive rather than antiviral (recognizing a bacterial metabolic product presented on the conserved MR1 molecule rather than MHC) (Le Bourhis *et al.*, 2013). Yet, MAIT cells possess the ability to produce Interferon (IFN)- γ , a potent antiviral cytokine, in a TCR-independent manner to a combination of IL-12 and IL-18 (Ussher *et al.*, 2014), suggesting a further role in antiviral defense. Furthermore, MAIT cells are specifically depleted in HIV infection (Cosgrove *et al.*, 2013; Leeansyah *et al.*, 2013) and have been implicated in the control of influenza through the production of IL-17 (Hamada *et al.*, 2009).

Impact on Vaccine Design

As indicated above, much of the incentive to understand T cell memory in more detail stems from a desire to develop novel vaccines, not only for complex viral targets such as HIV, but also for cancers, where induction of specific CD8⁺ T cell pools can be particularly effective. In the case of the latter, the

observation that PD-1 and similar inhibitory molecules can restrict effector functions during a persistent viral stimulus has been very informative in guiding novel therapies which block inhibitory functions *in vivo* (e.g., biologic agents blocking PD-1 and CTLA4 for use in human cancer immunotherapy) (Coulzin-Frankel, 2013).

The main aim of modern vaccine design is to induce specific immune responses that are long-lived and protective. In the case of T cell responses, this initiative is often hampered by a lack of knowledge of the 'correlates of protection.' This compares to protection mediated by antibodies, where reaching a certain titer of neutralizing antibody in the blood can be linked readily to protection against challenge. A number of features have been proposed which could contribute to protection, including: the frequency of antigen-specific cells, their functionality (notably secretion of multiple cytokines, including IL-2), and acquisition of markers of long-term memory. For some virus infections such as HIV, which infect mucosally, it has also been shown that induction of high frequencies of effector memory T cell populations – including those induced by novel CMV vectors – can be linked to immediate protective function (Hansen *et al.*, 2011). However, this remains a challenging area and each viral infection may require its own approach. Historically, the best vaccines have typically been live attenuated strains, where induction of T cells mirrors most closely the natural setting.

In the absence of a live attenuated virus, current technology to prime CD8⁺ T cell responses *in vivo* typically involve delivery of viral antigen from DNA – in the form of DNA vaccination, or delivered as a viral vector. A range of approaches have been used effectively in mice, but in humans currently the most efficient vectors appear to be those based on viral vectors such as primate adenoviruses. These are highly immunogenic, although in the case of HIV vaccines some of these approaches have been halted by lack of efficacy and concerns that immune activation induced by such vectors may increase the risk of HIV infection.

Conclusions and Future Directions

The understanding of T cell memory has developed enormously from a phenomenological approach to a much better molecular understanding of the transcriptional drivers and metabolic changes associated with generation of long-lived antigen-specific lymphocyte pools. Further work is required in the future to link these data – which nicely describe the cellular changes required for memory maintenance and function – to protection against challenge. However, as illustrated in this article, the rules that govern protection may differ subtly between different virus challenges and thus it may prove difficult to provide a one-size-fits-all model for protective memory. Furthermore, much of the focus to date has been on CD8⁺ T cell pools and much more detail is required on the parallel CD4⁺ T cell memory pools to provide a complete picture. If, as current data suggest, such antiviral (or vaccine-induced) memory for both CD4⁺ and CD8⁺ T cells exists as a continuum, then perhaps defining the protective qualities of T cells at different regions within this continuum could be an achievable aim.

Nuclear Factor of Activated T Cells and Tolerance

F Macian, Albert Einstein College of Medicine, Bronx, NY, USA

Introduction

The Nuclear Factor of activated T cells (NFAT) family of transcription factors encompasses five different proteins. Four of them are regulated by calcium signaling and termed NFATc1 (also known as NFAT2), NFATc2 (NFAT1 or NFATp), NFATc3 (NFAT4 or NFATx), and NFATc4 (NFAT3), while the activation of a fifth NFAT protein, NFAT5 (TonEBP), responds predominantly to hypertonic stress (Hogan *et al.*, 2003; Macian, 2005). At least one NFAT protein is expressed in any cell type or tissue to regulate a number of cell processes that range from developmental programs, cell differentiation or activation to modulation of responses to the extracellular environment (Crabtree and Olson, 2002). In T cells NFAT proteins were initially described as essential factors required to upregulate the expression of cytokine genes induced following T cell activation. Further studies started to uncover the wide range of cellular functions in which NFAT plays a regulatory role, which include almost all aspects of T cell biology. This article will focus on the different ways in which NFAT controls immune tolerance by regulating distinct aspects of the programs that control T cell activation.

NFAT Domain Structure

All calcium-regulated NFAT proteins contain three distinct domains. An N-terminal NFAT-homology region constitutes the regulatory domain of NFAT. This domain is moderately conserved among the different NFAT proteins and contains the regions that modulate NFAT activation, including phosphorylation sites, calcineurin docking sites, nuclear localization signals, and nuclear export signals; as well as the major transactivation domain. Following the N-terminal domain lies the Rel-homology region, which shares structural homology with the DNA-binding domain of Rel proteins and is highly conserved among all NFAT family members. This Rel-homology region not only contains the DNA-binding domain, which determines the binding specificity of NFAT, but also most of the residues involved in supporting many of the interactions of NFAT proteins with their transcriptional copartners, as well as the amino acids that maintain the contacts that allow for the formation of NFAT dimers. The C-terminus is not conserved among NFAT proteins and has been shown in some family members to be involved in mediating interactions with other transcription factors (Rao *et al.*, 1997; Macian, 2005). As opposed to the calcium-regulated NFAT proteins, NFAT5 is activated in response to osmotic stress and forms an obligated homodimer, much like the Rel proteins. Nevertheless, the DNA-binding domain of NFAT5 has 43% homology with the DNA-binding domain of the other NFAT family members and recognizes similar binding motifs on the DNA (Lopez-Rodriguez *et al.*, 2001). However, as no role has been attributed so far to NFAT5 in the regulation of immune tolerance, this article will focus on the calcium-regulated NFAT

factors expressed in T cells, which have been implicated in regulation of T cell activation and tolerance.

Regulation of NFAT Activation

The activation of all calcium-dependent NFAT proteins is regulated by their phosphorylation status (Okamura *et al.*, 2000). NFAT is maintained in the cytosol as a heavily phosphorylated protein. Phosphorylation occurs at a series of serine residues localized in the N-terminal regulatory domain and it is mediated by cytosolic kinases, such as casein kinase 1 (CK1), that maintain the phosphorylation of cytosolic NFAT (Okamura *et al.*, 2004); and export nuclear kinases, including CK1 and glycogen synthase kinase 3 (GSK3), which requires prior priming of NFAT through phosphorylation mediated by protein kinase A (PKA) or the dual-specificity tyrosine phosphorylation regulated kinases (DYRK) (Beals *et al.*, 1997; Gwack *et al.*, 2006). In the cytosol, NFAT and NFAT-kinases associate in a supramolecular complex that includes among other proteins several members of the importin beta family of nuclear import proteins, the leucine-rich repeat kinase 2 (LRKK2) and the calmodulin-binding protein IQGAP1. The noncoding RNAs NRON and lincRNA act as scaffolds for that complex (Sharma *et al.*, 2011; Willingham *et al.*, 2005).

Several calcium-coupled receptors can activate NFAT in different cell types. In T cells it is the engagement of the T cell receptor (TCR) that constitutes the main signaling event that leads to the activation of NFAT. As a result of recognition of antigen by the TCR, activation of phospholipase C gamma (PLC γ) causes the hydrolyzation of phosphatidylinositol-4,5-bisphosphate into Inositol 1,4,5-trisphosphate (IP3) and diacylglycerol. IP3 binds its receptor in the endoplasmic reticulum (ER), which causes exit of calcium from the ER into the cytosol. Depletion of the ER intracellular calcium stores is sensed by stromal interaction molecules 1 and 2 (STIM1 and 2) at the ER membrane, which move then closer to the plasma membrane to activate calcium-release activated calcium (CRAC) channels, which are formed by oligomers of ORAI1 proteins and are ultimately responsible for the store-operated calcium entry of extracellular calcium into the cytosol (Feske, 2007; Feske *et al.*, 2006). Docking of calcium-bound calmodulin on calcineurin causes activation of this protein-phosphatase that is responsible for the concerted dephosphorylation of multiple serine residues in the N-terminal domain of NFAT. This causes a conformational change in NFAT that leads to the exposure of one or more nuclear localization signals to allow the nuclear translocation of NFAT (Okamura *et al.*, 2000). It has been recently shown that activation-induced generation of reactive oxygen species plays also an important role in the regulation of the amplitude of the TCR-induced calcium signaling that mediates NFAT activation (Sena *et al.*, 2013). Once in the nucleus NFAT proteins bind sites in the promoters or enhancers of genes where they will form either cooperative complexes with other transcription

Figure 1 Regulation of nuclear factor of activated T cells (NFAT) activation. NFAT is maintained in the cytosol as heavily phosphorylated protein through the activity of cytosolic kinases and export nuclear kinases. Engagement of the T cell receptor (TCR) activates phospholipase C gamma ($PLC\gamma$) that converts phosphatidylinositol-4,5-bisphosphate (PIP2) into Inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG). IP3 binds its receptor (IP3R) in the endoplasmic reticulum (ER) which depletes this intracellular calcium store. This is sensed by stromal interaction molecules (STIM) that activate the calcium-release activated calcium channels that are formed by ORAI proteins. This leads to entry of extracellular calcium into the cell and activation of the phosphatase calcineurin (Cn) by calcium-bound calmodulin (Cm) to dephosphorylate multiple serine residues in the N-terminal domain of NFAT. This causes a conformational change that exposes nuclear localization signals and nuclear translocation of NFAT. In the nucleus NFAT proteins bind sites in the promoters or enhancers of genes where they will form complexes with other transcription factors (TF) to direct the expression of genes responsible for the development, differentiation or activation of T cells. NFAT may also form dimers to regulate the expression of genes that induce T cell inactivation and lead to the establishment of tolerance.

factors or NFAT dimers, to induce the expression of genes involved in the regulation of T cell development, differentiation, activation or tolerance (Feske *et al.*, 2001; Muller and Rao, 2010; Figure 1). Additional levels of regulation have also been reported to control NFAT activity. For instance, NFAT sumoylation regulates NFAT subnuclear localization and transcriptional activity, while poly-ADP-ribose polymerase (PARP)-dependent ADP-ribosylation increases NFAT DNA-binding activity (Olabisi *et al.*, 2008; Terui *et al.*, 2004).

A unique mechanism is also in place to regulate the expression of the short isoform of NFATc1 (NFATc1/A). The expression of most NFAT proteins, including the long isoforms of NFATc1, is constitutive in T cells. However, a positive autoregulatory loop controls the transcription of NFATc1/A, which accounts for the increased expression of this protein in activated T cells (Chuvpilo *et al.*, 2002).

NFAT-Regulated Transcription

The transcriptional activity of NFAT proteins is modulated by the partners with which they interact. NFAT does not bind DNA nor activate gene transcription as an independent

monomer, relying on interaction with other transcription partners to form active complexes. This property positions NFAT as a major hub for signal integration. Coordinated activation of calcium signaling with other signaling pathways to regulate specific cell functions is frequently attained in T cells through cooperation of calcium-activated NFAT with other transcriptional factors activated in response to specific signals (Macian, 2005). For instance, during T cell activation heterotrimeric NFAT/Activator protein 1 (AP-1) complexes, formed by an NFAT molecule interacting with Fos and Jun, are required for efficient induction of the expression of many cytokine genes that contain NFAT/AP-1 composite binding sites on their promoter or enhancer regions (Jain *et al.*, 1993; Macian *et al.*, 2000). This complex allows for integration of signals mediated by the TCR and costimulatory receptors, which lead to concomitant engagement of calcium signaling and the protein kinase C (PKC)/mitogen activated protein kinase (MAPK) signaling pathways, required for the activation of NFAT and AP-1, respectively. Similar mechanism of signal integration are responsible for the formation of complexes of NFAT with many other transcription factors, such as IRF4, GATA3 or p300, to regulate a wide range of cell functions that include, among others, T helper cell differentiation, cell

migration, cell cycle regulation, and cell death and survival (Avni *et al.*, 2002; Garcia-Rodriguez and Rao, 1998; Macian, 2005; Rengarajan *et al.*, 2002a).

As mentioned above the DNA-binding domain of NFAT proteins show structural identity with the DNA-binding domain of Rel proteins (Serfling *et al.*, 2004). Similar to members of the Rel family of transcription factors, that form obligated dimers to bind DNA, NFAT proteins have also been shown to have the ability to dimerize and bind to specific sites that contain two tandem NFAT-binding sites separated by a spacer formed by one or two bases (Jin *et al.*, 2003). These dimers direct the expression of distinct programs of gene expression that, as opposed to the classically described integrative nature of NFAT-regulated transcription, depend solely on the activation of NFAT without requiring other signals. As it will be discussed below, NFAT dimers play an important role in the expression of genes that induce the establishment of T cell tolerance (Soto-Nieves *et al.*, 2009).

Functions of NFAT in T cells

Although this article focuses on the role of NFAT in the regulation of T cell tolerance, the functions of this family of transcription factors in the modulation of the immune response are not limited to T cells and extend to the regulation of the activation and differentiation of many other cells that are involved in the generation of innate and adaptive immune responses, including B cells, dendritic cells, NKT cells, NK cells, macrophages, mast cells, or neutrophils (Muller and Rao, 2010).

The first NFAT protein to be cloned, NFATc2, was initially described as a transcription factor that bound the *Il2* gene promoter during T cell activation to, in cooperation with Fos and Jun, induce the expression of that cytokine gene (Jain *et al.*, 1992). Subsequent studies have identified NFAT proteins as ultimate targets of the signaling pathways that control the expression of many cytokine genes in T cells, therefore becoming central players in the regulation of T cell activation. Initial studies analyzing the phenotypes of mice with deletions of single NFAT proteins revealed smaller effects than expected on the responses of mature T cells to activation, suggesting certain level of functional redundancy (Ranger *et al.*, 1998a; Xanthoudakis *et al.*, 1996). The existence of this redundancy became more evident when mice deficient in two or more NFAT proteins were generated (Peng *et al.*, 2001; Rengarajan *et al.*, 2002b). For instance, the loss of NFATc1 and NFATc2 in T cells resulted in a profound defect on the ability of those cells to produce cytokines or generate cytolytic activity following TCR engagement (Peng *et al.*, 2001).

By controlling the expression of lineage specific cytokines as well as by acting in functional cooperation with transcription factors that influence lineage commitment, NFAT proteins also participate in the regulation of T helper cell differentiation. Sustained IL-4 production in activated naïve NFATc2 or NFATc2 + NFATc3-deficient T cells skews their differentiation toward a T helper type 2 (T_H2) phenotype, whereas T cells with a deletion of the gene encoding for NFATc1 appear to tilt the differentiation process toward T_H1 (Kiani *et al.*, 1997; Ranger *et al.*, 1998a; Rengarajan *et al.*, 2002b). NFAT has

also been shown to regulate the expression of IFN γ , IL-17 or IL-21, and therefore modulate T_H1 and T_H17 differentiation (Kiani *et al.*, 2001; Kim *et al.*, 2005; Liu *et al.*, 2004). Furthermore, cooperative interactions between NFAT and transcription factors that mediate T helper cell lineage commitment or direct NFAT-dependent regulation the expression of such transcription factors, such as GATA3, Tbet or ROR γ t, also underlie the central role of NFAT in the regulation of T helper cell differentiation (Avni *et al.*, 2002; Hermann-Kleiter and Baier, 2010; Kim *et al.*, 2014).

This positive effect of NFAT on T cell activation and effector differentiation is thought to account for the immunosuppressive activity of the commonly used inhibitors of calcineurin, such as cyclosporine A, which, by blocking calcium-calcineurin dependent NFAT dephosphorylation, prevent NFAT nuclear translocation and the activation of NFAT-dependent gene expression in T cells (Jain *et al.*, 1993).

NFAT and T Cell Tolerance

Studies performed in the last 10 years have revealed that NFAT proteins not only regulate the induction of positive effector T cell functions but they also play an essential role in the induction of tolerance (Baine *et al.*, 2009; Serfling *et al.*, 2006). The ability of NFAT to control two opposite functional programs in T cells resides in specific properties of these transcription factors that include their ability to regulate thymocyte selection, direct the differentiation of regulatory T cells and their ability to cooperate with many other transcription factors and form alternative transcriptional complexes activated under specific conditions in T cells to direct the expression of programs of gene expression that mediate a diverse set of responses including self-antigen induced T cell inactivation (Figure 2).

Thymocyte Development and Positive Selection

Several NFAT proteins are expressed early during thymocyte development, and regulate key steps in thymocyte maturation. Survival signals are transduce through NFAT activation and are required to ensure double negative to double positive transition (Adachi *et al.*, 2000; Oukka *et al.*, 1998). This is accomplished not only through canonical calcium-calcineurin-mediated activation of NFAT but also by other pathways, which include IL-7-receptor induced activation of NFATc1 or IKK-regulated expression of NFAT5. Activation of those NFAT proteins guarantees the survival of double negative thymocytes and their progression to CD4 + CD8 + double positive cells (Berga-Bolanos *et al.*, 2013; Patra *et al.*, 2013). The important role of NFAT proteins during thymocyte positive selection is also underscored by studies that have analyzed the consequences of the deletion of calcineurin or specific NFAT proteins in thymocytes, which result in marked defects in positive selection (Neilson *et al.*, 2004; Oukka *et al.*, 1998; Ranger *et al.*, 1998b). In some of these models, such as in the NFATc3- or the double NFATc2/NFATc3-deficient mice, peripheral mature T cells show a hyperactivated state that, while it may respond in part to defects in mechanisms of peripheral

Figure 2 Nuclear factor of activated T cells (NFAT) regulates T cell tolerance at different levels. NFAT proteins are required to ensure double negative (DN) thymocyte survival and the transition to double CD4⁺ CD8⁺ (DP) stage. NFAT also controls positive selection contributing to shaping the peripheral T cell receptor (TCR) repertoire. Expression of Foxp3 in regulatory T cells (Treg) is regulated by NFAT, which forms complexes with Smad3 to direct the expression of that gene. NFAT also cooperates with FoxP3 to regulate the expression of many of the FoxP3-controlled genes that define the Treg phenotype. Moreover, expression of NFAT-dependent genes induced by the presence of Treg during conventional T cell (Tconv) activation ensures efficient inhibition of effector functions in Tconv. NFAT dimers formed in response to suboptimal stimulation in CD4⁺ or CD8⁺ T cells are responsible for the expression of inhibitory gene that cause the induction of anergy in Tconv.

tolerance, it is likely also due to altered thymocyte selection in those mice.

Regulatory T Cells

Regulatory T cells (Treg) constitute a complex population of T cells that have a fundamental role in the maintenance of immune tolerance. Natural or thymic Treg, which develop in the thymus, and peripheral Treg, generated from naïve CD4⁺ T cells in the periphery, have the ability to suppress the activation of self-reactive T cells and several other cell types, and by doing so, prevent the development of uncontrolled

immune reactions against self (Wing and Sakaguchi, 2010). FoxP3 is the transcription factor that acts as the master regulator of Treg development and its function and expression are regulated by NFAT. NFAT forms part of the complex of transcription factors that bind to the enhancers that direct the expression of FoxP3 during Treg development (Tone *et al.*, 2008). Consequently mice bearing T cells which either fail to efficiently activate store-operated calcium entry or have deletions in the genes that encode for one or more NFAT proteins, have reduced levels of Tregs (Oh-Hora *et al.*, 2008; Vaeth *et al.*, 2012). NFAT involvement in the regulation of Treg function extends to at least two other aspects. First, NFATc2

has been shown to form complexes with FoxP3 to either repress or activate the expression of different genes, and, therefore, cooperate with FoxP3 in establishing a Treg-specific program of gene expression (Wu *et al.*, 2006). Furthermore, the suppressive activity of Tregs on effector CD4+ T cells appears to be dependent on the ability of Tregs to induce the expression of NFAT-dependent genes, which inhibit effector cytokine production and cell proliferation in suppressed T cells (Bopp *et al.*, 2005; Shin *et al.*, 2014).

T Cell Anergy

In response to suboptimal stimulation, T cells do not engage a 'full activation' gene expression program but instead upregulate the expression of a series of genes that encode proteins that have the ability to either inhibit signaling pathways downstream of the TCR or directly suppress the transcription of cytokine genes. As a consequence cells become anergic and respond poorly to new encounters with antigen (Macian *et al.*, 2002). The expression of this program of gene expression is directly or indirectly dependent on NFATc2 and includes genes such as those encoding for the ubiquitin ligases Grail, Cbl-b or Itch, which through targeting of specific signaling intermediates induce the degradation or functional inactivation of different signaling pathways downstream of the TCR; caspase 3, that selectively cleaves signaling proteins in anergic cells without inducing apoptosis; diacylglycerol kinase, which inhibits diacylglycerol-dependent signaling in T cells; the histone deacetylase Sirt1, which inhibits AP-1 activation; or the transcriptional repressors Ikaros and TLE4, which directly suppress IL-2 and IFN γ expression, respectively (Valdor and Macian, 2013). The expression of the transcription factors Egr2 and 3 is also upregulated in an NFAT-dependent manner in anergic T cells, where they directly regulate the expression of several anergy inducing factors, including Cbl-b and Sirt1 (Safford *et al.*, 2005; Zhang *et al.*, 2009). As discussed above, the ability of NFAT to direct two opposite programs, T cell activation and tolerance, results from the coordinated activation or lack of thereof of NFAT-transcriptional partners. This will determine which program will be engaged in each situation. During a full activation, likely to occur when pathogen-derived antigens are presented by activated dendritic cells, engagement of TCR and costimulatory receptors, especially CD28, will cause the activation of, among other transcription factors, NFAT and AP-1. These form a high-affinity complex that binds composite sites present in promoters and/or enhancers of many genes expressed in activated T cells. On the other hand, suboptimal activation due to reduced expression of costimulatory ligands on dendritic cells that have not been activated by danger signals (as it is likely to happen when self-antigens are processed) and/or the engagement of coinhibitory receptors in T cells and/or the presence of Treg, leads to the activation of NFAT without concomitant full AP-1 activation. In this context NFAT forms dimers that bind to NFAT-dimer sites present in the regulatory regions of anergy-associated genes (Soto-Nieves *et al.*, 2009). These dimers are not formed in activated T cells due to the much higher affinity of NFAT for Fos and Jun to form NFAT/AP-1 complexes, which prevents the expression of anergy-associated genes in activated T cells (Baine *et al.*, 2009). Although most studies performed so far have tried to decipher

how NFAT controls the induction of anergy in CD4+ T cells, evidence also supports that NFAT activity is required to induce tolerance in CD8+ T cells and B cells (Barrington *et al.*, 2006; Fehr *et al.*, 2010).

Recently, the physiological relevance of this process has been demonstrated in the context of cancer-induced tolerance. Induction of T cell tolerance is a common mechanism of immune evasion in many tumors. Studies using NFATc2 or Egr2 deficient mouse models have shown that T cells from those mice become resistant to tumor-induced tolerance, which results in efficient control of tumor growth (Abe *et al.*, 2012; Zheng *et al.*, 2012). The activation of the NFAT-dependent anergy-inducing program of gene expression in tumor infiltrating T cells likely results from the existence of inefficient transient contacts between dendritic and T cells in the tumor microenvironment, as has been shown for CD8+ T cells (Marangoni *et al.*, 2013). These fast contacts would result in maintained NFAT activation, due to delayed nuclear export, in the absence of AP-1, which requires more stable contacts to become activated.

Conclusions

- NFAT proteins play central roles not only in the regulation of positive programs of T cell differentiation and activation but also in the control of T cell tolerance.
- Integration of multiple signaling inputs results from the ability of NFAT proteins to form transcriptional complexes with different transcription factors, which allows NFAT to regulate specific programs of gene expression through partner selection and control T cell development, differentiation, activation, and tolerance.
- Members of the NFAT family of transcription factors participate at different levels in the regulation of immune tolerance, including the regulation of thymocyte selection, the differentiation of Treg, and the induction of T cell anergy.
- The multiple, and frequently opposite, roles that NFAT proteins play in the regulation of the adaptive immune response highlight the importance of the need to design targeted therapies that can affect certain functions without altering others.

Glossary

Acquired immunity An antigen-specific immune response mounted by B and T cells, which is tailored to specific pathogens (e.g., virus, bacteria). Also called adaptive immunity.

Apoptosis Programmed cell death, which can be part of normal developmental or regulatory processes, and can be altered in disease processes (e.g., many leukemias/lymphomas have mutations that enhance cell survival).

B cells Lymphocytes that play a key role in humoral immunity, where their main function is to produce antibodies.

Chemokines A subset of cytokines, which primarily induce immune cell chemotaxis.

Cytokines Small, secreted proteins that coordinate the immune response by affecting immune cell function.

Gene amplification An increase in the copy number of a given gene from the normal diploid state, a situation that occurs frequently for select genes in cancer cells.

Immunoglobulin Another name for an antibody.

Inflammation A complex biological response to pathogens, cell damage, or irritants. Characterized by vascular changes leading to swelling, heat, pain, and soreness.

Innate immunity First line of defense against pathogens, mediated primarily by macrophages and dendritic cells, which recognize conserved molecules on pathogens.

Isotype switching The process by which the type of antibody produced by a B cell changes from one class to another (e.g., switches from IgM to IgG).

Oncogene A viral or cellular gene that can transform a cell from a normal to a cancerous state. These genes are usually mutant versions of a normal cellular gene (the proto-oncogene).

Signal transduction A multicomponent process by which a biochemical signal (often an extracellular ligand) is converted through a series of cytoplasmic protein intermediates into a change in gene expression within the nucleus of a cell, which then alters some process of cellular physiology.

Single nucleotide polymorphism (SNP) A single nucleotide sequence variation in genomic DNA that distinguishes groups of individuals within a population. SNPs are often used as predictors of disease susceptibility or other biological differences between individuals.

T cells Lymphocytes that play the central role in cell-mediated immunity.

Transformation The process by which a normal cell is converted into a malignant cell.

Transcription factor A protein that can bind to specific sites on DNA to increase or decrease expression of a nearby gene.

Introduction

The mammalian NF- κ B (nuclear factor of κ B site binding) transcription factor family comprises the related cellular proteins p50/p105, p52/p100, c-Rel, p65 (aka RelA), and RelB (Table 1). These proteins form homodimers or heterodimers, which can alter the expression of nuclear genes, often ones involved in cellular processes, such as development, cell survival, cell proliferation, and immunity (Gilmore, 2006).

The N-terminal halves of all NF-kappaB (NF- κ B) proteins consist of a conserved DNA-binding/dimerization domain called the Rel homology domain (RHD) (Figure 1(a)). Sequences C-terminal to the RHD can be used to subdivide the NF- κ B family into those that contain a transactivation domain (c-Rel, RelA, RelB), which is required for activation of target gene expression, versus those that contain C-terminal ankyrin repeats (p50/p105, p52/p100), which inhibit the DNA-binding activity of these transcription factors. NF- κ B proteins have also been found in invertebrates, including insects (e.g., *Drosophila melanogaster*), cnidarians (e.g., sea anemones, corals, and hydra), sponges, and some single-celled premetazoans (e.g., choanoflagellates and Capsaspora) (Gilmore and Wolenski, 2012).

In most normal cells, NF- κ B dimers are located in the cytoplasm in an inactive state bound to an inhibitor called I κ B (inhibitor of NF- κ B) (Figure 1(b)). There are several mammalian I κ B proteins (Table 1), which have different affinities for the various NF- κ B dimers and different cell-specific expression patterns. A large number of extracellular signals initiate intracellular signal transduction pathways that lead to I κ B degradation, which enables NF- κ B to enter the nucleus to bind specific DNA sequences and activate or, less often, repress target gene expression. Activation of NF- κ B can be divided into two general pathways, which are distinguished by the upstream activating kinases and by the NF- κ B dimers that are induced. In the classical (or canonical) NF- κ B pathway, inducers activate cytoplasmic I κ B kinase β (IKK β), which phosphorylates an I κ B protein (e.g., I κ B α , β , ϵ), leading to its degradation by the proteasome; this process induces nuclear translocation of specific NF- κ B complexes, generally p50-RelA and p50-c-Rel. In the alternative (or noncanonical) NF- κ B pathway, inducers activate IKK α , which phosphorylates residues on the p52 precursor p100, leading to degradation of the p100 inhibitory ankyrin repeat domain by the proteasome; this process induces nuclear translocation of p52-RelB dimers. In many cases, these two NF- κ B pathways are simultaneously

induced, but in others, specific activators induce only one of the pathways.

As described in this article, NF- κ B plays a key developmental and functional role in innate and acquired immune cell function as well as inflammation. Importantly, nuclear NF- κ B activation is normally transient in almost all cells, a state achieved by a wide variety of regulatory mechanisms (Hayden and Ghosh, 2011, 2014). Consistent with the need to tightly control NF- κ B activity, in a variety of chronic inflammatory and malignant diseases, NF- κ B is constitutively active and located in the nucleus. Similarly, in certain genetically based human immunodeficiencies, NF- κ B signaling is defective.

NF- κ B in Normal Immune Cell Function and Development

NF- κ B Expression and Knockout Mice

NF- κ B plays key roles in B- and T-cell development, the generation of secondary lymphoid organs (e.g., the spleen and lymph nodes), and the function of many immune cell types (e.g., B cells, T cells, natural killer T cells, dendritic cells (DCs), and macrophages) (Hayden and Ghosh, 2011; Vallabhapurapu and Karin, 2009). NF- κ B transcription factors are expressed in all cell types; however, in many cases their highest levels of expression are in immune cells. In general, p50 and RelA are expressed in all cell types, and the p50–RelA dimer is the NF- κ B complex that is induced in most non-hematopoietic cells. On the other hand, high levels of p52/p100, c-Rel, and RelB expression are restricted to a variety of hematopoietic cells. That is, p52/p100 is expressed at the highest levels in the thymus and spleen, c-Rel levels are high in certain B- and T-cell subtypes, myeloid cells, and erythroid cells, while high levels of RelB are found in lymphoid cells of the thymus, spleen, and small intestine (Peyer's patches).

Much of what is known about the function of NF- κ B in immune cells comes from the study of genetically modified mice (knockouts or KOs) lacking specific NF- κ B subunits

(Gerondakis *et al.*, 2006). With the exception of RelA KO mice, which die embryonically, mice with KOs of other individual NF- κ B subunits are viable with their most prominent phenotypes being alterations in immune cell function (Table 2). The distinct phenotypes of mice with KOs of each NF- κ B subunit demonstrate that each subunit has a unique function. Several mouse models missing multiple NF- κ B subunits have also been created, and generally the phenotypes of mice missing multiple NF- κ B subunits are exaggerated compared to the single KO strains (Gerondakis *et al.*, 2006).

nfk1 KO mice

Mice with a KO of the *nfk1* gene encoding p50/p105 are viable, but have a variety of defects in acquired and innate immune cells (Sha *et al.*, 1995). Various B-cell subtypes (e.g., marginal zone and B1 cells) are reduced in number or have impaired function (e.g., follicular B cells). As a consequence, *nfk1* KO mice mount a poor humoral immune response to certain microbial molecules (e.g., lipopolysaccharide (LPS)) and have abnormal immunoglobulin (Ig) isotype switching. Most types of T cells develop normally in *nfk1* KO mice, although T helper-cell differentiation is partially defective and CD8 memory T-cell development is enhanced in these mice. Innate immune cells are also differentially affected in *nfk1* KO mice: for example, macrophages show reduced expression of certain cytokines (e.g., IL-6, IL-10), whereas natural killer cells have enhanced function. Because of these mixed immune cell phenotypes, *nfk1* KO mice show a range of responses to different pathogens and stresses as compared to wild-type mice: in some cases, *nfk1* KO mice are more susceptible to a given pathogen, and in other cases, they have unchanged or enhanced responses.

nfk2 KO mice

nfk2 KO mice lack the mature p52 protein, as well as the p100 precursor protein. These mice develop normally and are viable and fertile as adults (Caamaño *et al.*, 1998; Franzoso *et al.*, 1998). Nevertheless, they have defective spleen and

Figure 1 (a) Structures of NF- κ B superfamily proteins. Shown are the general structures of the two subclasses of NF- κ B proteins. All NF- κ B proteins contain an N-terminal DNA-binding/dimerization domain (green) called the Rel homology domain (RHD). At the C-terminus of the RHD there is also a sequence essential for nuclear localization (N). The C-terminal halves of the NF- κ B precursors p105 and p100 contain an ankyrin repeat (ANK) domain (red bars), which must be removed by proteolysis to activate the DNA-binding activity of the NF- κ B subunits p50 and p52, respectively. The C-terminal halves of Rel proteins contain transactivation domains, which are not removed upon activation. The stand-alone I κ B proteins consist largely of ANK repeats, which enable them to bind to and inhibit NF- κ B dimers. (b) General outline of the canonical and noncanonical pathways for activation of NF- κ B transcription factors (see text for more details).

lymph node architecture, impaired B-cell maturation and survival, as well as defective T cell, macrophage, dendritic cell, and natural killer cell functions. Given that p52–RelB is the primary dimer of the alternative NF- κ B pathway, it is not surprising that many of these immune cell defects appear to be due to loss of alternative NF- κ B signaling. Thus, many of the defects seen in *nfkb2* KO mice are also seen in KO mice lacking upstream activators of alternative NF- κ B signaling (e.g., BAFF, the lymphotoxin β receptor or NIK (NF- κ B-inducing kinase)) or missing RelB, the dimeric partner of p52.

c-rel KO mice

The c-Rel protein is expressed most highly in B and T cells. Mice with a *c-rel* gene knockout are viable and fertile, but have

multiple mature immune cell defects that make these mice more sensitive to infection (Gilmore and Gerondakis, 2011). Defects in *c-rel* KO mice that contribute to this phenotype include impaired B-cell proliferation, survival, and isotype switching in response to B cell-activating signals such as antigen receptor and CD40 stimulation. These B-cell deficiencies are due in part to c-Rel regulation of specific genes important for cell division (e.g., E2F, cyclin E, c-Myc) and the inhibition of cell death (e.g., A1, Bcl-XL).

Although T cells in *c-rel* knockout mice have proliferation defects due to impaired antigen and co-stimulatory (CD28) receptor signaling, the extent of the T-cell effects are immune signal dependent (Gerondakis et al., 2006). For example, T cells in *c-rel* KO mice do not proliferate in response to *Toxoplasma gondii*, but do proliferate in response to influenza. c-Rel is also important for the development of immune-suppressive CD4 regulatory T (Treg) cells, with the numbers of Treg cells reduced by approximately sixfold in *c-rel* KO mice (Gerondakis et al., 2014). Nevertheless, the Treg cells that do develop in c-Rel KO mice have normal T cell-suppressive functions, which may explain why these mice fail to develop autoimmune disease despite reduced numbers of Treg cells (Gilmore and Gerondakis, 2011). Of note, the loss of c-Rel function can also be beneficial. For example, the immune response defects seen in *c-rel* KO mice render them less susceptible to certain experimental inducers of arthritis (Gerondakis et al., 2006), and pathology arising from IL-17-dependent inflammatory responses controlled by T helper cells is reduced in *c-rel* KO mice due to c-Rel's role in Th17 differentiation (Chen et al., 2011).

rela KO mice

Full animal KO of the *rela* gene is embryonically lethal because of extensive liver apoptosis, which occurs due to the sensitivity of embryonic hepatocytes to the cell-killing effects of circulating tumor necrosis factor (TNF) in the absence of expression of RelA-dependent anti-apoptotic protective genes (Beg et al., 1995; Beg and Baltimore, 1996). However, a role for RelA in other cell types has been demonstrated through the use of RelA/TNF-receptor double KO mice or by transplanting RelA KO hemopoietic stem cells into wild-type mice. Through such studies, RelA has also been found to be important for the survival of macrophages, B cells, and T cells, as well as for the development of secondary lymphoid organs including the spleen and lymph nodes (Gerondakis et al., 2006).

relb KO mice

Mice with the *relb* gene knocked out are plagued by a large number of primary and secondary lymphoid cell and organ defects and multiple immune cell defects (Weih et al., 1995). For example, *relb* KO mice lack Peyer's patches or germinal centers in the spleen, due to the failure of the TNF superfamily of cytokines to activate p52–RelB dimers. *relb* KO mice also lack certain types of dendritic cells and natural killer T cells, while B cells exhibit functional defects. Moreover, many organs show extensive T-cell and innate immune cell infiltration that coincides with inflammation-induced tissue damage. Collectively, these multiple defects in the immune system lead to a reduction in the life span of mice lacking RelB (Weih et al., 1995).

Important NF- κ B-Activating Pathways in Acquired Immunity

B- and T-cell receptor pathways

Several induced processes that are important for B- and T-cell function require activation of NF- κ B. In particular, stimulation of the B-cell receptor (BCR) and T-cell receptor (TCR) by antigen promotes immune cell expansion by turning on cell proliferation, cell survival, and lymphocyte maturation pathways (Schulze-Luehrmann and Ghosh, 2006). Although both of these antigen receptor pathways proceed through the canonical NF- κ B pathway, the molecules upstream of the NEMO (NF- κ B essential modulator)–IKK complex are distinct (Hayden *et al.*, 2006).

CD40

CD40 is a TNF receptor family member that is expressed on the surface of B cells, which are activated during antigen-dependent B- and T-cell interactions through CD40 ligand–CD40 engagement. This interaction results in activation of NF- κ B, which promotes B-cell division, survival, isotype switching, and plasma cell differentiation (Hayden and Ghosh, 2014). Unlike most receptors, CD40 engages both the classical and alternate NF- κ B pathways in B cells.

BAFF receptor pathway

The TNF superfamily cytokine B cell-activating factor (BAFF) binds to three distinct receptors (BAFF-R, TACI, and BCMA) mainly expressed to varying degrees on B cells of different maturity. Signaling through BAFF-R and BCMA promotes the survival and proliferation of B cells by activating NF- κ B dimers downstream of the classical and alternate pathways (Rickert *et al.*, 2011).

CD28 receptor pathway

T-cell activation and survival is enhanced by CD28, a receptor for B7.1 and B7.2, ligands expressed on antigen presenting cells. CD28–B7 interactions enhance T-cell function in part by promoting transcription of the gene encoding the cytokine IL-2, which depends on classical NF- κ B dimers comprising c-Rel, RelA, and NF- κ B1 (Cheng *et al.*, 2011).

Role of NF- κ B in Innate Immunity

The innate immune system is the first line of defense against microbial pathogens, functioning to identify infectious agents and rapidly eliminate them. This initial response to infection is characterized by numerous activities including cellular communication via secreted cytokines, homing of immune cells (e.g., neutrophils and natural killer (NK) cells) along chemokine gradients to sites of infection, secretion of acute-phase proteins by the liver, and production of pro-inflammatory molecules (e.g., nitric oxide and prostaglandins). NF- κ B plays a central role in many of these responses, acting early in macrophages and dendritic cells that first sense pathogens to drive expression of inflammatory and immune regulatory genes, while also functioning in other cell types (e.g., liver cells and vascular endothelial cells) to mediate various cellular responses to pro-inflammatory cytokines (Dev *et al.*, 2011). The function of NF- κ B in the innate immune response is conserved throughout vertebrate evolution, and indeed, some of the components of innate immunity are found in insects, such as *Drosophila*, suggesting that the control of the host-defense responses is one of the earliest functions of NF- κ B signaling. The receptors of the human innate immune system that activate NF- κ B are listed in Table 3.

Table 3 Innate immune receptors that activate NF-κB

Receptor family	Cellular location	Number in humans	Ligands
TLR	Plasma membrane	9	Lipids, proteins, nucleic acids
NLR	Cytosolic	6	Peptidoglycans, microbial toxins
RLR	Cytosolic	2	Viral RNA

Abbreviations: NLR, NOD-like receptor; RLR, RIG-I-like receptor; TLR, toll-like receptor.

**Figure 2** Summary of major classes of innate and acquired immune processes controlled by activation of NF-κB (see text for more details).

A defining feature of the innate immune response is the recognition of invading pathogens through a host of conserved pathogen-associated molecules. Sentinel cells in our immune system, such as macrophages and dendritic cells, express a range of specialized receptor molecules for detecting pathogen components. The Toll-like receptors (TLRs) are a family of plasma membrane-spanning proteins that bind a range of pathogen-association molecules, such as the bacterial cell-wall component lipopolysaccharide or unmethylated DNA (Kawasaki and Kawai, 2014). In the cytoplasm, NOD-like receptors (NLR) (Saxena and Yeretssian, 2014) bind bacterial molecules such as peptidoglycans and RIG-I-like receptors (Reikine *et al.*, 2014) recognize viral RNA. Upon ligand binding, all of these pathogen-detection receptors activate NF-κB, which in turn increase the expression of target genes encoding effectors of the innate immune response, such as the pro-inflammatory signaling molecules (e.g., TNF and interleukin 1-beta (IL-1β)), proteins involved in microbial killing (e.g., defensins), chemokines that coordinate immune cell migration (e.g., interleukin 8 (IL-8)), and proteins involved in inflammation (e.g., nitric oxide synthase (iNOS) and cyclooxygenase enzyme 2 (COX2)). This central role of NF-κB in the initial response to pathogen detection remains conserved in other organisms; in *Drosophila*, TLR engagement can activate an NF-κB-like pathway that activates a number of antimicrobial genes called cecropins (Ganesan *et al.*, 2011).

In addition to initiating the innate immune response, NF-κB functions in a variety of cells that respond to the pro-inflammatory cytokines by mediating signaling downstream of IL-1 and TNF receptors. Liver cells respond to IL-1 and TNF by producing and secreting acute-phase proteins that have broad immune effects including pathogen opsonization by complement proteins and inhibition of microbial growth. Vascular endothelial cells respond to IL-1 and TNFα by up-regulating

Table 4 Some NF-κB target genes important in immune cell processes

Functional category	Target gene product
Anti-apoptosis	Bcl-2, Bcl-xL, A1/Bfl-1, IAP
Cytokines	TNF-α, IL-1β, IL-6, IL-8, IFNβ
Chemokines	CCL5
Cell cycle/cell proliferation	Cyclin D1, E2Fa
Adhesion	VCAM, ICAM, E-selectin
Enzymes	MMP1, iNOS, COX-2
Transcription factors	Foxp3, c-Myc, c-Rel, IRF4, NFAT

Abbreviations: Bcl, B-cell lymphoma; CCL5, chemokine (C-C motif) ligand 5; COX-2, cyclooxygenase-2; IAP, inhibitor of apoptosis; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; iNOS, inducible nitric oxidase synthetase; IRF, interferon regulatory factor; MMP1, matrix metalloproteinase-1; NFAT, nuclear factor of activated T cells; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule.

molecules, such as E-selectin, ICAM-1, and VCAM-1, needed for leukocyte trafficking to sites of infection. These diverse cellular responses, all mediated by NF-κB in response to pro-inflammatory cytokines, are central to the coordinated response to infection. Thus, NF-κB plays a key role at the center of the innate immune response (Figure 2).

Misregulation of NF-κB in Human Immune Diseases

Given the important role that NF-κB plays in normal immune cell function, it is perhaps not surprising that it is disrupted in many diseases that involve altered immunity or inflammation. In general, these diseases rely on defective or chronic NF-κB signaling, which results in changes in the normal NF-κB-dependent regulation of target gene expression. Some of the key genes that are involved in normal and pathological NF-κB-dependent immune and inflammatory responses are listed in Table 4.

Increased NF-κB Activity in Chronic Inflammatory Diseases

The key role that NF-κB plays in initiating and maintaining normal acute inflammatory responses explains its prominent role in many chronic inflammatory diseases. Most, if not all, chronic inflammatory diseases show increased NF-κB activity, which clearly contributes to the disease. One of the best characterized examples of NF-κB's role in inflammatory disease is Crohn's disease, which can be caused by mutations in a cytoplasmic pathogen receptor gene, *NOD2*. These disease-associated mutations cause *NOD2* to become a constitutive activator of NF-κB-dependent inflammation (Saxena and Yeretssian, 2014).

Single nucleotide polymorphisms (SNPs) at the *REL*, *NFKB1*, and *NFKBIA* (encoding I κ B) locus have been associated with several human autoimmune diseases, including arthritis, psoriasis, celiac disease, and inflammatory bowel disease (Table 5; Gilmore and Gerondakis, 2011; Sun and Zhang, 2007). However, whether these genetic changes play an active role in these diseases is not clear.

Decreased NF- κ B Activity in Human Immunodeficiency Diseases

Mutations that abrogate activation of NF- κ B have been found in several human immunodeficiencies. In particular, mutations in several genes that lead to defective activation of the TLR pathway are associated with reduced responsiveness to pathogens (Frans *et al.*, 2014). In one of the best characterized examples, mutations in the *IKBKG* gene lead to immunodeficiencies. The *IKBKG* gene encodes a scaffold protein (NEMO) that interacts with and is required for activation of the I κ B kinase by a variety of upstream signals to lead to activation of NF- κ B. Mutations that inactivate NEMO function, and thus lessen NF- κ B activation, are primarily associated with the immunodeficiency syndromes of ectodermal dysplasia and incontinentia pigmenti (Courtois and Israël, 2011).

Increased NF- κ B Activity in Immune Cell Cancers

Many B- and T-cell leukemias and lymphomas have constitutively high levels of nuclear NF- κ B DNA-binding activity and consequently increased NF- κ B target gene expression (see Table 5). The increased NF- κ B activity can arise from a variety of mechanisms: (1) point mutations in genes that activate or

inhibit NF- κ B, (2) gene amplification, (3) autocrine or paracrine stimulation, and (4) possibly epigenetic mechanisms.

Activation of NF- κ B by point mutations in signaling pathway genes has been studied extensively in diffuse large B-cell lymphoma (DLBCL) and multiple myeloma (Staudt, 2010). In DLBCL, mutations that lead to chronic activation of NF- κ B are commonly found amongst proteins in the BCR-to-NF- κ B pathway, and include activating mutations in the BCR, adaptor proteins (CARD11, MALT1, BCL10), and inactivating mutations in I κ B (Staudt, 2010). Moreover, one subclass of DLBCL, called the activated B-cell (ABC) subtype, is characterized by activated NF- κ B that results in cells from ABC-DLBCL being particularly sensitive to growth inhibition by a variety of NF- κ B inhibitors (Staudt, 2010). Similarly, multiple myeloma cells have a variety of mutations in cytoplasmic regulators of NF- κ B signaling and anti-NF- κ B compounds inhibit their growth (Gilmore, 2007).

The *REL* gene (encoding human c-Rel) is frequently amplified in several types of human B-cell lymphoma, including DLBCL, Hodgkin's lymphoma and follicular lymphoma, and less frequently in T-cell lymphoma (Gilmore and Gerondakis, 2011). Mutations in *REL*, *RELA*, and *NFKB2* have also been described in B-cell lymphomas, multiple myeloma, and T-cell lymphoma, respectively (Courtois and Gilmore, 2006). Moreover, some human lymphoma cells have inactivating mutations in the gene encoding I κ B, and such mutations cause NF- κ B to be constitutively active. Of note, the *v-rel* oncogene carried by the avian Rev-T retrovirus rapidly transforms a variety of avian hematopoietic and lymphoid cells *in vitro* and *in vivo* (Gilmore, 1999), and overexpression of human c-Rel can directly transform animal lymphoid cells in culture (Gilmore and Gerondakis, 2011).

Human Immune Cell Viruses Use NF- κ B for Replication and Pathogenesis

Several human viruses utilize NF- κ B for their replication or pathogenesis in immune cells (Gilmore and Mosialos, 2003). In one of the best characterized examples, human immunodeficiency virus type-1 (HIV-1), the causative agent of acquired immunodeficiency syndrome (AIDS), has two NF- κ B binding sites in its promoter and these sites are required for efficient expression of viral genes in several cell types (Chan and Greene, 2012). Moreover, activation of NF- κ B in immune cells following infection by other pathogens may, at least in part, be responsible for reactivation of HIV-1 gene expression, leading to the escape from viral latency seen in many HIV-1-infected individuals. In other cases, viruses encode proteins that can intrude into cellular signaling pathways to activate NF- κ B. For example, Epstein-Barr Virus (EBV), which is associated with Burkitt's B-cell lymphoma, encodes the LMP1 protein that mimics the ability of CD40 to activate NF- κ B, which is required for EBV's B-cell transforming effect (Ersing *et al.*, 2013). Similarly, the Tax protein of the human T-lymphotrophic virus type 1 (HTLV-1) interacts with several cellular proteins to activate IKK and cause chronic activation of NF- κ B, a process that is required for the T-cell transforming activity of HTLV-1 (Cheng *et al.*, 2012).

Table 5 Human immune-related diseases associated with alterations in NF- κ B signaling

Disease	NF- κ B activity	Molecular changes
B-cell lymphoma	Increased	<i>REL</i> amplification; <i>NKFB2</i> , <i>BCL3</i> , <i>REL</i> mutation; Upstream signaling mutations
T-cell lymphoma	Increased	<i>REL</i> amplification; <i>NKFB2</i> , <i>BCL3</i> , <i>REL</i> mutation
Multiple myeloma	Increased	<i>RELA</i> , <i>NFKB1</i> , <i>NFKB2</i> mutations; Upstream signaling mutations
Chronic inflammatory (arthritis, psoriasis, celiac disease, inflammatory bowel disease)	Increased	<i>REL</i> , <i>NFKB1</i> , <i>NFKBIA</i> SNPs; <i>NOD2</i> mutations
Immunodeficiencies (incontinentia pigmenti; ectodermal dysplasia)	Decreased	<i>IKBKG</i> and <i>IKBA</i> mutations; Upstream signaling mutations

Targeting NF- κ B for Therapy in Immune Diseases

There are approximately 1000 molecules that have been reported to inhibit NF- κ B signaling and ones that block almost every step in the NF- κ B pathway have been described (Gilmore and Garbati, 2010). Many natural products that have been ascribed anti-inflammatory, antiaging, and anticancer properties have been shown to block NF- κ B activation in cell-based studies (Luqman and Pezzuto, 2010). In most cases, it is not clear whether such substances exert disease protective effects through inhibition of NF- κ B. To cite a few examples, natural products with proposed biological activity and anti-NF- κ B activity include an active green tea component epigallocatechin-3-gallate, curcumin, and many other food ingredients with antioxidant activity.

Between approximately 1990 and 2005, there was considerable interest in developing anti-NF- κ B pharmaceuticals, primarily for the treatment of cancer and inflammation. Many of these studies sought to target IKK, as a central mediator of NF- κ B signaling and because of successes in targeting other protein kinases. Although several such compounds showed success in cell-based or animal studies, they have not been particularly successful in clinical trials. At least in part, this is because inhibition of IKK can promote liver cancer and unexpectedly also induced systemic inflammation (Luedde *et al.*, 2007). However, proteasome inhibitors, which probably act in part by inhibiting NF- κ B activation through blocking I κ B degradation, have shown some success in the treatment of multiple myeloma (Lawasut *et al.*, 2012). NF- κ B subunit-specific inhibitors may hold more promises for future therapy. While such compounds do not currently exist for each NF- κ B subunit, a recent report on a c-Rel-specific inhibitor that blocks graft versus host disease in mouse recipients of bone marrow transplants (Shono *et al.*, 2014) lends considerable weight to this therapeutic strategy.

Discovery of Dendritic Cells

Ralph Steinman was the first to describe the functional properties of a very rare cell type, the dendritic cells (DCs) (Steinman and Cohn, 1973; Steinman and Nussenzweig, 1980). In 2011, Steinman was awarded the Nobel Prize for his discoveries (Banchereau *et al.*, 2011; Steinman, 2012). DCs are localized throughout the body, equipped with a variety of Fc receptors (FcR) and specialized pattern recognition receptors (PRR) for sensing and recognition of invading pathogens. These PRRs include Toll-like receptors (TLR), C-type lectin receptors (CLR), nucleotide-binding oligomerization domain receptors (NOD), and retinoic-inducible gene 1-like receptors (RIG-I) (Kawai and Akira, 2008, 2011; Akira *et al.*, 2006; Figdor *et al.*, 2002; Chopin *et al.*, 2012; Elinav *et al.*, 2011; Yoneyama and Fujita, 2009; Nimmerjahn and Ravetch, 2006, 2008; Guillemins *et al.*, 2014a). Upon antigen encounter, DCs engulf antigens from their surroundings by macropinocytosis, phagocytosis, or receptor-mediated endocytosis (Burgdorf and Kurts, 2008; Roche and Furuta, 2015; Trombetta and Mellman, 2005; Guemnonprez *et al.*, 2002; Savina and Amigorena, 2007). Direct contact to microbial products induces DC maturation processes including the upregulation of MHC class II co-stimulatory molecules (e.g., CD80 (B7-1), CD86 (B7-2)), and activation markers (e.g., CD40 and CD83) (Kamath *et al.*, 2000; Cao *et al.*, 2005) as well as the secretion of cytokines (Vega-Ramos *et al.*, 2014; Kurts *et al.*, 2010). In addition, chemokine receptors, such as CCR7, are upregulated and facilitate DC migration to secondary lymphoid

tissues, for the presentation of processed antigens (Förster *et al.*, 1999; Dieu *et al.*, 1998). As most important antigen presenting cells, DCs are able to bridge the gap between innate and acquired immunity by inducing primary immune responses, thereby initiating lifelong immunological memory to the invading pathogen (Banchereau and Steinman, 1998). On the other hand, DCs are able to maintain peripheral tolerance against self-antigens (Hawiger *et al.*, 2001; Steinman and Nussenzweig, 2002). DC antigen presentation under steady state conditions leads to elimination or anergy (durable non-responsiveness) of the interacting, potentially auto-reactive T cells and thereby to protection from autoimmune responses (Steinman *et al.*, 2003; Steinman and Nussenzweig, 2002; Schwartz, 2003).

The presentation of antigens occurs in the immunological synapse in a complex either with the major histocompatibility molecule type I or II (MHC-I and MHC-II), thus allowing for recognition of the peptide antigen either by CD8⁺ T cells or CD4⁺ T cells, respectively. Importantly, only professional antigen presenting cells (or certain types of nonprofessional antigen presenting cells) are able to present antigens as peptide MHC class II complexes (pMHC-II) on their cell surface (Shortman and Liu, 2002; Heath and Carbone, 2001; Mellman and Steinman, 2001; Villadangos and Schnorrer, 2007; Villadangos, 2001; Joffre *et al.*, 2012; Merad *et al.*, 2013; Konermann *et al.*, 2012). The specific combination of the antigen presenting DC subtype, origin of activation stimulus, and the secretion of DC subset specific cytokines directs T cell priming and determines the fate of a CD4⁺ T helper cell to

become a T_H1 , T_H2 , T_H17 , or regulatory T cell, thereby indirectly influencing the assembly and production of antigen-specific antibodies by B cells. In the following sections, the major classical and alternative antigen presentation pathways will be discussed in more detail.

Antigen Processing and Presentation

Classical MHC Class I Processing

Almost all nucleated cell populations express MHC class I (MHC-I) molecules on their surfaces. Cells that have down-regulated MHC-I or express high levels of NK cell activating receptors are eliminated by NK cells (Lanier, 2005; Diefenbach *et al.*, 2001). This can be observed during carcinogenic transformation of normal cells into tumor cells or as a consequence of viral infection. The MHC-I molecule is of pivotal importance for the presentation of antigens to cytotoxic $CD8^+$ T cells. In order to present antigens on the cell surface as peptide MHC class I complexes (pMHC-I), cytoplasmic antigens have to be proteolytically cleaved within the proteasome, transported into the lumen of the endoplasmic reticulum (ER), and subsequently loaded onto freshly synthesized MHC-I molecules (Bjorkman *et al.*, 1987). These pMHC-I complexes are transported via the Golgi network to the cell surface (Joyce, 1997).

Under steady state conditions, a multicatalytic protease, the so-called proteasome, generates MHC-I peptides from different substrates, such as defective ribosomal products (DRiPs), viral components, as well as error-free short- and long-lived proteins (e.g., transcription factors). The quantitative contribution of DRiPs to the pool of degradable proteins is still under debate (Rock *et al.*, 2014; Yewdell *et al.*, 1996; Schubert *et al.*, 2000). The 26S proteasome contains a 20S core and two 19S outer compartments (Arrigo *et al.*, 1988; Voges *et al.*, 1999). The core consists of 28 subunits, which are structured into four heptameric rings containing the outer α -subunits and inner proteolytically active β -subunits, namely $\beta1$, $\beta2$, and $\beta5$ (Kloetzel and Ossendorp, 2004). The polyubiquitination of misfolded proteins flags them for recognition by the 19S compartment (Loureiro and Ploegh, 2006; Kloetzel and Ossendorp, 2004; Lecker *et al.*, 2006; Metzger *et al.*, 2014). Unfolded proteins reach the inner 20S compartment for initial degradation (Cascio *et al.*, 2001). Most of the resulting peptide fragments are reduced to peptides <8 residues in length, in particular by the cytosolic metalloendopeptidase thimet oligopeptidase (TOP) (Saric *et al.*, 2001; York *et al.*, 2003). As a result, the majority of peptides are too small for MHC-I loading, therefore lost for antigen presentation and might be rather reused for protein biosynthesis (Rock *et al.*, 2004). However, a small fraction of peptides escapes destruction or just experiences cytosolic peptide-trimming. The membrane-bound heterodimeric TAP-1/TAP-2 complex (adenosine-triphosphate (ATP) dependent transporter associated with antigen processing (TAP)) transports these peptides from the cytosol into the lumen of the endoplasmic reticulum (ER). Here TAP associates with Tapasin (TAP-binding protein) and the MHC-I complex, consisting of an α -chain and a β_2 -microglobulin molecule (Wearsch and Cresswell, 2008). Only

a minor percentage of the translocated antigens has been fully processed by the proteasome (Lucchiari-Hartz *et al.*, 2000). Evidence arises that most epitope precursor peptides, which have entered the ER, require further N-terminal trimming to the appropriate amino acid (aa) length of 8–9 residues by the heterodimeric complex of ER-resident aminopeptidases 1 and 2 (ERAP1; ERAP2) (Chang *et al.*, 2005; Evnouchidou *et al.*, 2014; Weimershaus *et al.*, 2013; Schatz *et al.*, 2008; Kanaseki *et al.*, 2006; Rock and Goldberg, 1999; Kisselev *et al.*, 1999). Noteworthy, both peptide length and sequence are crucial for a successful $CD8^+$ T cell response (Ekeruche-Makinde *et al.*, 2013; Burrows *et al.*, 2006; Cole *et al.*, 2010; Schumacher *et al.*, 1991). Before loading of the processed peptides onto the MHC-I molecule, the latter has to be assembled. Therefore, the two chaperones Calnexin and Calreticulin stabilize the MHC-I α -chain after its co-translational insertion into the ER membrane. Further, Erp57 joins this complex and ensures proper folding of the MHC-I α -chain and association of the β_2 microglobulin (Zhang *et al.*, 2006b). All these molecules belong to the peptide-loading complex (PLC) (Wearsch and Cresswell, 2008). Loading of the peptide onto an MHC-I molecule results in a stable conformation and the dissociation from the PLC. The pMHC-I complex enters the Golgi network to be transported to the cell surface, where it is presented to $CD8^+$ T cells (Jensen, 2007; Janeway, 1992). The presentation of pMHC-I complexes is strictly dependent on the TAP transporter. Only in some rare cases a pMHC-I presentation might be possible in DCs without TAP (Joffe *et al.*, 2012).

Classical MHC Class II Processing

In contrast to the formation of pMHC-I complexes, only professional antigen presenting cells, especially DCs, are able to process and present peptides of antigenic proteins as peptide MHC class II complexes (pMHC-II) on their cell surface for the induction of $CD4^+$ T cell responses (Cella *et al.*, 1997; Pooley *et al.*, 2001; Shortman and Liu, 2002; Mellman and Steinman, 2001; Villadangos and Schnorrer, 2007; Merad *et al.*, 2013). Professional antigen presenting cells are specialized in the uptake of extracellular antigens and the formation of so-called intracellular phagosomes or early endosomes (Burgdorf and Kurts, 2008; Roche and Furuta, 2015; Trombetta and Mellman, 2005; Guernonprez *et al.*, 2002; Savina and Amigorena, 2007). Based on our current knowledge, at least four different internalization routes of exogenous antigens can be described: clathrin-mediated or caveolae-dependent endocytosis, phagocytosis, and macropinocytosis (Trombetta and Mellman, 2005; Roche and Furuta, 2015).

Cell surface receptors involved in receptor-mediated endocytosis recycle back to the plasma membrane (recycling endosomes), while the engulfed antigens are further processed (Roche and Furuta, 2015). Therefore, the antigen-containing early endosomes (as well as macropinosomes and phagosomes) fuse with a late endosomal/lysosomal antigen processing compartment. Characteristically, this organelle is a multivesicular body (MVB), with many small intraluminal vesicles generated by the endosomal sorting complexes required for transport (ESCRT) that contain ubiquitinated membrane proteins. Additionally, the low pH and the

presence of proteolytic enzymes foster the assembly of pMHC-II complexes (Roche and Furuta, 2015; Trombetta and Mellman, 2005; Luzio *et al.*, 2010).

Similar to the proteolytic cleavage of proteins by the proteasome for the subsequent loading onto MHC class I molecules in the ER, exogenous antigens also require particular pre-processing steps. First, the gamma interferon-inducible lysosomal thiolreductase (GILT), which shows a maximum activity in an acidic environment of pH 4–5, reduces protein disulfide bonds to free thiols and therefore enhances further antigen processing (Phan *et al.*, 2000; Maric *et al.*, 2001; Arunachalam *et al.*, 2000). Depending on the antigen presenting cell subpopulation (thymic epithelial cells, DCs, monocytes, macrophages, B cells, among others), a set of endosomal/lysosomal proteases has been described to be involved in antigen processing and function for MHC class II presentation (Chapman, 2006) such as cathepsin B, C, D, E, F, H, K, L, S, V, W, X, as well as the asparaginyl endopeptidase (AEP, also called legumain) (Chapman, 2006; Riese and Chapman, 2000; Manoury *et al.*, 1998; Conus and Simon, 2010; Honey and Rudensky, 2003). This group of proteases, comprising endopeptases, carboxy-, and aminopeptidases, fulfills various functions in the context of antigen processing in professional antigen presenting cells. Cathepsins are of crucial importance, since their dysregulation generates major perturbations of the immune system homeostasis (Nakagawa *et al.*, 1999; Conus *et al.*, 2008; Mohamed and Sloane, 2006). Therefore, cathepsins have become interesting targets for clinical treatment approaches (Yasuda *et al.*, 2005).

MHC-II molecules, consisting of an α -chain and a β -chain, are assembled within the ER, where they form nonamers of three MHC-II α/β heterodimers and three invariant chains (I_i , CD74) (Newcomb *et al.*, 1996). The latter is not only needed to stabilize the newly synthesized MHC-II protein chains, but also to protect the nascent MHC-II molecule from premature association with peptides in the MHC-II binding cleft before reaching the endosome. Further, the invariant chain routes the MHC-II- I_i complex into endosomal organelles (Bakke and Dobberstein, 1990). These compartments are also referred to as the MHC-II compartment (MIIC). In these compartments, I_i is proteolytically cleaved by AEP and cathepsin S in DCs, to yield the CLIP fragment (class II-associated invariant chain peptide). AEP has been shown to be involved in the initiation phase of I_i cleavage, while cathepsin S is responsible for further degradation of I_i and CLIP fragment formation (Nakagawa *et al.*, 1999; Manoury *et al.*, 1998; Watts *et al.*, 2005; Riese *et al.*, 1996; Riese and Chapman, 2000). As this last step should be controlled to protect from unwanted processing and potential loading of self-antigens onto MHC-II, the endogenous inhibitor Cystatin C (CyC) regulates the function of cathepsin S (Pierre and Mellman, 1998; El-Sukari *et al.*, 2003). Interestingly, it could be shown that murine splenic CD11c⁺ DCs contain lower levels of lysosomal proteases (e.g., cathepsin L, S, D, B, and AEP) in comparison to peritoneal lavage macrophages, which was correlating with a prolonged presentation of immunogenic peptides (Delamarre *et al.*, 2005).

Finally, the CLIP fragment is removed by the chaperone HLA-DM, and thereby peptides within the late endosome/lysosome gain access to the binding cleft of MHC-II (Riese and Chapman, 2000; Conus and Simon, 2010; Colbert *et al.*, 2009). In DCs, B cells, and thymic epithelial cells, the non-

polymorphic HLA-DR (mouse: MHC-II) like molecule HLA-DO influences the function of HLA-DM, thereby promoting self-tolerance (Fallas *et al.*, 2004; Poluektov *et al.*, 2013; Denzin, 2013). Upon DC stimulation pMHC-II complexes, now in a stable conformation, follow a microtubular transport from the antigen processing compartment to the cell surface for the presentation to CD4⁺ T cells (Chow *et al.*, 2002). Interestingly, this transport seems to be adjustable as a proportion of pMHC-II complexes can be specifically ubiquitinated by the E3 ligase MARCH 1. Thereby, pMHC-II complexes are transferred to the lysosomal compartments for their degradation, while only a minor fraction of the pMHC-II complexes reach the surface (Mintern *et al.*, 2015; Moffat *et al.*, 2013a).

Cross-Presentation

Cross-presentation describes a process uniquely found in subsets of DCs, in which extracellular antigens, such as viral or tumor antigens, which were engulfed by pinocytosis, phagocytosis or receptor-mediated endocytosis, are presented on MHC-I molecules to CD8⁺ T cells (Dudziak *et al.*, 2007; den Haan *et al.*, 2000; Pooley *et al.*, 2001; Brossart and Bevan, 1997; Villadangos *et al.*, 2007; Rock and Shen, 2005; Joffre *et al.*, 2012; Segura and Amigorena, 2014; Kamphorst *et al.*, 2010; Mintern *et al.*, 2015). This process was first described by Bevan (Bevan, 1976). Due to the shorter half-life of pMHC-I complexes (in comparison to pMHC-II) on the cell surface, the necessary DC activation and migration to draining lymph nodes, phagocytosed antigens require a delayed processing (Gil-Torregrosa *et al.*, 2004). van Montfoort *et al.* (2009) described an MHC-II[−]EEA1[−]LAMP1⁺ lysosome-like compartment in murine bone marrow derived DCs (BMDCs), different from the MIIC, in which exogenous antigen can be stored for several days, therefore creating a depot for sustained peptide delivery for cross-presentation (Martín-Fontecha *et al.*, 2003; van Montfoort *et al.*, 2009; Kreer *et al.*, 2012). In addition, attenuated antigen processing is facilitated in (not further defined) splenic and BMDCs due to lower concentrations of lysosomal proteases and inhibition of acidification (Delamarre *et al.*, 2005; Hotta *et al.*, 2006; Kreer *et al.*, 2012).

Overall, the detailed mechanisms of cross-presentation remain poorly understood, especially how engulfed antigens ‘escape’ the endosomal/lysosomal compartment for proteasomal degradation (Kreer *et al.*, 2012; Rodriguez *et al.*, 1999). Two major pathways of cross-presentation are under current debate: the ‘cytosolic’ and the ‘vacuolar pathway’ (Joffre *et al.*, 2012). For the first theory of cross-presentation, the ‘vacuolar pathway’ via the endocytic compartment, it was shown that this route can be abrogated by lysosomal inhibitors, but is resistant to proteasomal blockade and TAP-independent (Rock and Shen, 2005; Shen and Rock, 2004; Song and Harding, 1996). Therefore, it is believed that antigens following the ‘vacuolar pathway’ of cross-presentation are enzymatically dismantled within the endocytic compartment and loaded onto MHC-I molecules, which have been recycled from the cell surface.

The second mechanism, the ‘cytosolic pathway,’ is characterized by an egress of internalized antigens from the endosomal compartment into the cytosol. This process of antigen export is potentially conducted by the ATPase p97 and the

heterotrimeric SEC61 complex, which have been previously reported to be crucial for the retrotranslocation of misfolded proteins from the ER (ER associated protein degradation, ERAD) into the cytosol (Ackerman *et al.*, 2006; Smith *et al.*, 2011). After proteasomal degradation peptides are subsequently loaded in a TAP-dependent manner onto MHC-I molecules in the ER (Wearsch and Cresswell, 2008). In addition, several research groups have postulated that antigenic peptides are TAP-dependently transported back into the phagosomal/endosomal compartment (Guermonprez *et al.*, 2003; Houde *et al.*, 2003; Burgdorf and Kurts, 2008). It is further believed that regulatory protein SEC22b affects antigen cross-presentation; SEC22b is involved in membrane fusion processes and localized in the ER-Golgi intermediate compartment (ERGIC) as an ER resident soluble *N*-ethylmaleimide-sensitive-factor attachment receptor (SNARE). Interaction of SEC22b with the phagosomal syntaxin 4 facilitates the transfer of ER components, for example, the TAP complex (Cebrian *et al.*, 2011; Joffre *et al.*, 2012). Consequently, the cytosolic pathway of cross-presentation is sensitive to proteasome inhibitors (Kovacovics-Bankowski and Rock, 1995).

In the following further findings correlated with cross-presentation of antigens will be discussed. Data indicate that I α can colocalize with a nascent MHC-I molecule in the ER, instead of MHC-II, followed by a TAP-dependent transfer into the endolysosomal compartment and therefore facilitating cross-presentation of phagocytosed antigens (Basha *et al.*, 2012; Duan and Srivastava, 2012). Moreover, in recent years the existence of the endosomal insulin-regulated aminopeptidase (IRAP) has been elucidated. In analogy to the ER-resident ERAP molecules, endosomal IRAP is specialized in aminoterminal trimming of peptides destined for cross-presentation in DCs (Saveanu *et al.*, 2009; Weimershaus *et al.*, 2012; Segura and Villadangos, 2011).

Unexpectedly, Singh and Cresswell found that the gamma interferon-inducible lysosomal thiolreductase (GILT, also Ifi30), which is described to mediate pMHC-II presentation due to its ability to reduce protein disulfide bounds of engulfed antigens, is critically involved in a TAP-dependent cross-presentation of viral antigens. This activity seemed to be dependent on the protein sequence of the engulfed antigen (Singh and Cresswell, 2010). Whether this is a DC subset specific feature still needs to be determined.

Another way of regulating cross-presentation of antigens has been shown to be influenced by the activity of an alternative proteasome in interferon- γ or interferon- α treated human monocyte derived DCs (moDCs) or BMDCs, but also primary CD11c⁺ DCs, in which the 19S subunit is replaced by the 11S cap, and the active β -subunits β 1, β 2, and β 5 of the 20S subunit are replaced by LMP2, MECL1 (LMP10), and LMP7, respectively (Hisamatsu and Shimbara, 1996; Fröh *et al.*, 1994; Tosello *et al.*, 2009; Bandoh *et al.*, 2005). This catalytical complex is called immunoproteasome and generates peptides with high affinity for MHC class I (Gaczynska *et al.*, 1994).

Autophagy

Autophagy is a crucial player in the maintenance of cellular homeostasis. The term 'autophagy' describes the engulfment

and subsequent endosomal/lysosomal proteolysis of long-lived proteins and the recycling of nutrients or defective organelles (Ravikumar *et al.*, 2010; Ciechanover, 2005; Filomeni *et al.*, 2014; Kroemer *et al.*, 2010). The observation that the cytoplasmic protein neomycin phosphotransferase II (NeoR) was no longer presented as peptide MHC-II complex on EBV transformed human B cells after blockade of the autophagosomal pathway indicated that autophagy is involved in antigen presentation of cytoplasmic proteins on MHC-II (Nimmerjahn *et al.*, 2003). In addition, evidence emerged that also cytosolic pathogens can follow the destruction in these acidic compartments, accompanied by a presentation on MHC-II complex by professional antigen presenting cells (Crotzer and Blum, 2010; Roche and Furuta, 2015). Up to date, there are three major mechanisms defined for lysosomal degradation of intracellular material: microautophagy, macroautophagy, and chaperone-mediated autophagy (CMA) (Mizushima *et al.*, 2008; Münz, 2009).

In the latter pathway the cytosolic chaperone heat shock cognate protein of 70 kD (HSC70) recognizes target peptide sequences. The unfolded target protein binds to the lysosomal membrane mediated by the help of a chaperone complex, including HSC70, HSP90, HSP40, Bag-1, Hip, and Hop (Münz, 2009). Multimeric lysosome-associated membrane protein-2A (LAMP-2A) and lysosomal HSC70 finally facilitate the protein translocation into the lumen of the lysosome for subsequent degradation (Cuervo and Dice, 1996; Agarraberes *et al.*, 1997).

The second mechanism, microautophagy, describes a process of direct inclusion of cytosolic material into the lumen of the late endosomal compartment followed by enzymatic hydrolysis. It further relies on the activity of ESCRT I and III, which conduct the invagination of the endosomal membrane for the formation of MVBs. The transport of the cytosolic cargo is mediated by the chaperone HSC70 (Sahu *et al.*, 2011).

The third mechanism of autophagy, the so-called macroautophagy, describes a process of vesicle formation around cytoplasmic constituents. A set of autophagy-related genes (Atg) such as Atg8/LC3 are involved in the assembly of the autophagosomal double-walled membrane and thereby in an increased presentation of peptides as pMHC-II complex (Schmid *et al.*, 2007). Researchers have identified Beclin-1 as a fundamental key player in the regulation of autophagy and apoptosis (Kang *et al.*, 2011). In addition, Atg5, Atg12, and Atg16L1 form another complex under the influence of the ubiquitin-like enzymes Atg7 (E1-like) and Atg10 (E2-like), which is associated with the outer membrane of the nascent autophagosome until completion (Mizushima *et al.*, 1998). The newly built autophagosome then fuses with endosomal and lysosomal compartments for the generation of amphisomes and autolysosomes, respectively (Fader and Colombo, 2009; Münz, 2009).

In professional antigen presenting cells, most of all in DCs, autophagy is a specific means to deliver cytoplasmic viral particles to intracellular compartments with subsequent MHC-II presentation, TLR stimulation, and proinflammatory cytokine production (Ireland and Unanue, 2011; Severa *et al.*, 2013; Li *et al.*, 2005; Morris *et al.*, 2011). Most knowledge on autophagy in DCs is based on data generated from BMDCs or MoDCs. Interestingly, Lee *et al.* could demonstrate in splenic

murine CD11c⁺ DCs that cross-presentation of peptides remained unaffected in the absence of Atg5, while MHC-II presentation and thereby CD4⁺ T cell induction was impossible due to an impaired phagosome-to-lysosome fusion (Lee *et al.*, 2010). This is a very interesting finding, which needs further clarification of DC subset specific differences.

Besides the classical MHC class I and II processing and presentation pathways, CD1 restricted, MHC-independent presentation mechanisms of lipid antigens have been described, but are excluded here (Barral and Brenner, 2007; Silk *et al.*, 2008).

DC Development and DC Characterization

The rapid progress in flow cytometry, mass cytometry, histocytometry, the conjugation of antibodies to varieties of fluorochromes and tandem conjugates, but also the development of multiple engineered fluorescent proteins as well as transcriptional and proteome profiling allowed for the discovery of a variety of cell subpopulations with specialized immune functions in the field of DC research (O'Donnell *et al.*, 2013; Perfetto *et al.*, 2004; Chattopadhyay and Roederer, 2012; Bendall *et al.*, 2012; Newell *et al.*, 2013; Eissing *et al.*, 2014; Gerner *et al.*, 2012; Edwards *et al.*, 2003; Lindquist *et al.*, 2004; Chattopadhyay *et al.*, 2008; Piatkevich and Verkhusha, 2011; Pandey *et al.*, 2013; Lundberg *et al.*, 2013; Xue *et al.*, 2014; Meissner and Mann 2014; Heim *et al.*, 1995; Tsien 1998; Vander Lugt *et al.*, 2014; Miller *et al.*, 2012; Watchmaker *et al.*, 2014). Today it is known that all (murine) DC subpopulations originate from hematopoietic progenitor cells generated in the bone marrow, or yolk sac/fetal liver at earlier developmental stages (Geissmann *et al.*, 2010; Doulatov *et al.*, 2010; Shortman and Naik, 2007; Liu and Nussenzweig, 2010). In this process the hematopoietic stem cell (HSC) differentiates into a common lymphoid (CLP) and a common myeloid progenitor (CMP) (Liu and Nussenzweig, 2010; Shortman and Naik, 2007). CMPs give rise to a monocyte macrophage DC progenitor (MDP), which generates different monocyte subpopulations and a common DC progenitor (CDP) (Liu and Nussenzweig, 2010; Karsunky *et al.*, 2003; Fogg *et al.*, 2006; Waskow *et al.*, 2008). At this point the CDP can further differentiate into terminally differentiated plasmacytoid DCs (pDCs) as well as precursors of classical/conventional DCs (preDCs). The latter ones leave the bone marrow into the blood and populate lymphoid tissues (lymph nodes, spleen, or Peyer's patches, but also bone marrow, and thymus) as well as non-lymphoid tissues (skin, mucosa, intestine, and lamina propria) (Geissmann *et al.*, 2010; Liu and Nussenzweig, 2010; Merad and Manz, 2009).

Besides their anatomical localization, lifespan, and origin, DCs can be phenotypically distinguished from other cell subpopulations by the absence of markers of the B (mouse: CD19 or human: CD19/CD20) and T cell lineage (CD3) as well as NK cell (NKp46, in humans also: CD56), erythrocyte (mouse: Ter119) and granulocyte/neutrophil lineage (mouse: Ly6G, human: CD66b), in combination with an expression of MHC-II in mice or of HLA-DR in humans, which are all of utmost importance for the identification and definition of DCs (Liu and Nussenzweig, 2010; Waskow *et al.*, 2008; Shortman

and Naik, 2007; Merad and Manz, 2009). Additional cell surface markers such as CD4, CD8, CD11b, CD11c, CD13, CD103, EpCAM, Langerin (human: CD1c (BDCA1 (Blood DC antigen)), CD123, CD141 (BDCA3), CD207 (Langerin) CD303 (BDCA2), CD370 (Clec9A)) are used for the definition of primary DC subpopulations (Liu and Nussenzweig, 2010; Merad and Manz, 2009; Figdor *et al.*, 2002; Satpathy *et al.*, 2012). Recent progress in DC ontogeny research supports the notion that DCs might be better distinguished from the monocyte and macrophage lineages based on the expression of transcripts for the tyrosine kinase receptor fms-like tyrosine kinase Flt3 (also Flk2 or CD135) and the zinc finger transcription factor (zbtb46) (Schraml and Reis e Sousa, 2015; Guilleams *et al.*, 2014b; Merad *et al.*, 2013).

Functional Specialization in Antigen Presentation of Mouse DC Subpopulations

DCs consist of a great family of different DC subpopulations expressing differential sets of cell surface receptors such as TLR, CLR, scavenger receptors, and FcR, all of them important for antigen recognition and/or antigen engulfment. On top, data indicate a DC subset specialization in antigen processing and presentation and thereby activation of differential cellular and humoral immune responses. Most information we have obtained on DC subset specialization is based on the original definition of DCs by cell surface marker expression. According to Merad and Manz, DCs can be separated into two groups. The first group consists of conventional or classical DCs (cDCs), which can be further distinguished into non-lymphoid tissue-migratory and lymphoid tissue-resident DCs. Overall, a clear definition of a cDC subset should consider its functional specialization and developmental origin. The second group is built by plasmacytoid DCs (Merad and Manz, 2009).

Plasmacytoid DCs

Plasmacytoid DCs (pDCs), also known as natural interferon-producing cells, separate early in development from the classical DC branch and are pivotal in the production of type I interferons after viral infections with distinct differences in their migratory capacities (Villadangos and Young, 2008). The pDC development is dependent on common regulators of DC development, such as Stat3, PU.1, E2-2, or Irf8 (Miller *et al.*, 2012; Satpathy *et al.*, 2011; Reizis *et al.*, 2011; Sawai *et al.*, 2013), while their lineage determination is dependent on the E2-2 (Tcf4) transcription factor (Reizis *et al.*, 2011). Recently, it could be shown that the migration of pDCs from the bone marrow into the peripheral organs strictly relies on the transcription factor Runx2 (Sawai *et al.*, 2013).

Besides their plasma cell morphology, characteristic murine pDC cell surface molecules are PDCA-1, SiglecH, and CD45RA/B220, with an intermediate or absent expression of CD11c and a complete absence of most conventional DC lineage markers (Zhang *et al.*, 2006a; Merad and Manz, 2009). As pDCs are the main producers of type I interferons in response to viral infection, TLR7 and 9 ligands or specific

microbial stimuli, they have an important role in the activation of cells of the innate and the adaptive immune system such as T cells (Asselin-Paturel *et al.*, 2005; Swiecki and Colonna, 2010; Cervantes-Barragan *et al.*, 2012; Reizis *et al.*, 2011). pDCs can be found in bone marrow, blood, and lymphoid organs, and they can accumulate in diseased tissues. Studies have implicated that dysregulated pDCs might be involved in the pathogenesis of Sjögren's disease and lupus erythematosus (Rönnblom, 2010).

In contrast to cDCs, murine pDCs are regarded to be incapable of presenting pMHC-II complexes derived from exogenous antigens for a longer period of time to specific T cells, which is in contrast to data derived from human pDCs (Segura and Amigorena, 2014). This is due to the fact that MHC-II turnover and degradation are not downregulated in activated murine pDCs (Young *et al.*, 2008). However, this issue is under current debate, since evidence is emerging that murine pDCs can stimulate profound humoral and cellular immune responses in the presence of certain TLR stimulation (Loschko *et al.*, 2011). Interestingly, pDCs might be further separated into mature CCR9 negative and immature CCR9 positive pDCs (Hadeiba *et al.*, 2008; Wendland *et al.*, 2007). The latter ones have been described to be potent inducers of antigen specific regulatory T cells leading to suppression of antigen-specific immune responses under steady state conditions (Hadeiba *et al.*, 2008). Interestingly, in dependency on pMHC-II presentation the same subset was described to induce mixed Th1/Th2 CD4⁺ responses after *in vivo* delivery of antigens to the pDC surface receptor bone marrow stromal antigen-2 (Bst-2/CD317/PDCA-1) under immunostimulatory conditions. Furthermore, in a model for the depletion of conventional DCs, without affecting pDCs, the delivery of antigens to Bst-2 on pDCs indicated that these cells might only be capable of inducing CD4⁺ T cell responses (Sapozhnikov *et al.*, 2007). This is in contrast to data published by Loschko *et al.*, who clearly demonstrated an antigen cross-presentation and CD8⁺ T cell response under stimulatory conditions (Loschko *et al.*, 2011b; Moffat *et al.*, 2013b). pDC specific depletion models might help to shed more light on the antigen processing and presentation capabilities of pDCs.

Most data on murine pDCs indicate an overall tolerogenic role in a variety of different tissues and autoimmune diseases (Bailey-Bucktrout *et al.*, 2008; de Heer *et al.*, 2004; Hadeiba *et al.*, 2008; Jongbloed *et al.*, 2009; Kang *et al.*, 2007; Ochando *et al.*, 2006; Goubier *et al.*, 2008). In line with these correlations, antigen delivery to the inhibitory sialic acid binding Ig-like lectin H (Siglec-H) molecule on pDCs induced rather tolerogenic antigen specific immune responses even in the presence of a strong immune stimulation, but without involvement of regulatory T cells (Loschko *et al.*, 2011b). Overall, the mechanisms how pDCs might process and present engulfed antigens still remain to be resolved.

Lymphoid Tissue-Resident DCs

Two major resident non-migrating conventional DC subsets, both expressing MHC-II and CD11c, can be found in the murine spleen and lymph nodes: CD8⁺CD11b[−] and CD8[−]CD11b⁺ DCs (Banchereau *et al.*, 2000; McLellan *et al.*,

2002; Merad and Manz, 2009; Vremec *et al.*, 1992; Pulendran *et al.*, 1999). They are reported to be also present with variations in their surface molecules in bone marrow, mucosal tissues, thymus, and liver (Iwasaki, 2007; Merad and Manz, 2009; Pulendran *et al.*, 2008). In the following both subset specifications in the process of antigen processing and presentation will be described in more detail.

CD8⁺CD11b[−] DCs

The CD8⁺CD11b[−] resident DC subset expresses DEC205 (CD205, Ly75), XCR 1 and Clec9A (DNNGR-1), is mainly localized in the white pulp T cell area (periarterial lymphoid sheets (PALS)), but also in the marginal zone of the murine spleen as well as in the lymph node T cell region (Gerner *et al.*, 2012; Kraal *et al.*, 1986; Idoyaga *et al.*, 2009; Dudziak *et al.*, 2007). The development of CD8⁺CD11b[−] DCs is strictly dependent on the presence of the transcription factors BATF3, IRF8, and Id2, while both CD8⁺CD11b[−] as well as CD8[−]CD11b⁺ DCs depend on the transcription factor Zbtb46 (Edelson *et al.*, 2011; Hildner *et al.*, 2008; Hashimoto *et al.*, 2011; Hacker *et al.*, 2003; McLellan *et al.*, 2002; Satpathy *et al.*, 2012; Meredith *et al.*, 2012). Interestingly, it was demonstrated that spleen resident CD8⁺CD11b[−] DCs can be further subdivided into CD8⁺CD103[−] and CD8⁺CD103⁺ DCs (McLellan *et al.*, 2002; Qiu *et al.*, 2009). Controversial data on the function of the latter ones described their ability to uptake blood borne apoptotic cells, which is a general feature of CD8⁺CD11b[−] DCs (Qiu *et al.*, 2009; Iyoda *et al.*, 2002). Notably, only in Balb/c mice CD8⁺CD103⁺ cells were also positive for Langerin (Idoyaga *et al.*, 2009; Qiu *et al.*, 2009). Kissenpfennig *et al.* (2005) also detected Langerin expression on thymic DCs and blood-derived CD8⁺CD11b[−] DCs in secondary lymphoid organs. Antibody immune complex engulfment, antigen protein uptake, but also *in vivo* antigen targeting studies using chimeric non-Fc receptor binding antibodies fused to an antigen of choice, revealed that in contrast to CD8[−]CD11b⁺ DCs murine CD8⁺CD11b[−] DCs are superior in cross-presentation and activation of CD8⁺ cytotoxic T cell responses (Iyoda *et al.*, 2002; Pooley *et al.*, 2001; Schnorrer *et al.*, 2006; Schulz and Reis E Sousa, 2002; Bonifaz *et al.*, 2002; Bonifaz *et al.*, 2004; Dudziak *et al.*, 2007; Idoyaga *et al.*, 2008; Soares *et al.*, 2007; den Haan *et al.*, 2000; Vander Lugt *et al.*, 2014). Notably, this was found to be correlating to an increased expression of molecules involved in the processing of antigens for MHC class I in CD8⁺CD11b[−] DCs (such as TAP1, TAP2, Tapasin, ERp57, Calreticulin, Calnexin, Sec61, and ERAAP). pMHC-I presentation of targeted antigens needed TAP transport as TAP deficient CD8⁺CD11b[−] DCs were unable to induce CD8⁺ cytotoxic T cell activation (Bonifaz *et al.*, 2002; den Haan *et al.*, 2000). Cystatin C is described as an inhibitor of cathepsin S and thereby a potential suppressor of MHC class II protein translocation and peptide loading. Although Cystatin C is overexpressed in MHC-II⁺LAMP1⁺ compartments of CD8⁺CD11b[−] DCs (Dudziak *et al.*, 2007; El-Sukkari *et al.*, 2003), data indicate that I_i degradation and MHC-II peptide loading of processed protein antigens was similar in isolated and cultured Cystatin C deficient CD8⁺CD11b[−] and CD8[−]CD11b⁺ DCs (El-Sukkari *et al.*, 2003). These data suggest that antigen cross-presentation might be superior in

CD8⁺CD11b[−] DCs and not directly dependent on Cystatin C expression.

Besides cell intrinsic features, the endocytic antigen uptake receptor might play a role in directing the processing and presentation capabilities in the DCs. Antigen targeting studies either using chimeric antibody antigen constructs or other antigen sources suggest that the binding site of the targeted receptor indirectly dictates the stability of the antigen, which might be due to differential routing of the antigens within the cell (Kreer *et al.*, 2012; Mintern *et al.*, 2015). It was further shown that both the CD8⁺CD11b[−] and the CD8[−]CD11b⁺ DC subset of human DEC205 receptor transgenic mice are able to cross-present ovalbumin antigen coupled to an anti-human DEC205 antibody, thereby indicating a specific role of the receptor in routing antigens (Kamphorst *et al.*, 2010). This is notable because CD8[−]CD11b⁺ DCs otherwise seem to be specialized for pMHC-II presentation (see below).

Overall, it is widely accepted that CD8⁺CD11b[−] DCs only use the cytosolic pathway for cross-presentation of antigens (Joffre *et al.*, 2012). In addition to the molecules involved in antigen processing for MHC-I, cross-presentation activity was demonstrated to be also dependent on the alkaline pH in the endosomal/phagosomal compartments in CD8⁺CD11b[−] DCs, thereby antigen degradation remains limited in this subset (Joffre *et al.*, 2012; Savina *et al.*, 2009). Data indicate that the cytosolic (p47phox) and membrane subunits (gp91phox and gp22phox) of the NADPH oxidase NOX2 assemble in CD8⁺CD11b[−] phagosomes, which leads to the production of reactive oxygen species (ROS) and thereby inhibition of phagosomal acidification. NOX2 recruitment was directly controlled by the small GTPase Rac2 (Savina *et al.*, 2009). All these data correlate with the finding that BATF3 deficient mice, which are missing the CD8⁺CD11b[−] DC subset, reveal less functional anti-viral and anti-tumor immune responses directly correlating with inefficient CD8⁺ T cell responses (Hildner *et al.*, 2008; Edelson *et al.*, 2010). Notably, antibody responses were not affected in these mice indicating a less pronounced function of CD8⁺CD11b[−] DCs in pMHC-II antigen presentation (Hildner *et al.*, 2008). Similar findings have been obtained by the use of a Langerin-DTR mouse, in which not only Langerin⁺ DCs from skin were depleted upon diphtheria toxin treatment, but also CD103⁺ and CD8⁺CD11b[−] lymphoid tissue DCs. In this mouse model, it became clear that those DCs are important for the priming of influenza, but also Leishmania, specific CD8⁺ T cell responses (GeurtsvanKessel *et al.*, 2008; Brewig *et al.*, 2009; Merad *et al.*, 2013). In addition to their ability to cross-present antigens to CD8⁺ cytotoxic T cells, CD8⁺CD11b[−] DCs are prominent producers of IL-12 upon stimulation, which is important for the differentiation of CD4⁺ T cells into T_H1 cells. Interestingly, even in T_H2 prone Balb/c mice T_H1 responses were promoted by CD8⁺CD11b[−] DCs (Soares *et al.*, 2007; Pulendran *et al.*, 1999; Maldonado-López *et al.*, 1999). As a 'signal 3' IL-12 is also crucial for 'classical cognate licensing' of CD8⁺ T cell responses, a process that involves the simultaneous recognition of linked antigens by a CD4⁺ helper T cell and a cytotoxic CD8⁺ T cell, thereby avoiding misguided cytotoxic CD8⁺ T cell activation and memory (Thaïss *et al.*, 2011; Schulz *et al.*, 2000). Moreover, under non-inflammatory conditions it was demonstrated that CD8⁺CD11b[−] DCs are

able to release TGF- β , which regulates the production of regulatory CD4⁺ T cells in the periphery, and thereby identifying CD8⁺CD11b[−] DCs as key players for the maintenance of peripheral T cell tolerance (Yamazaki *et al.*, 2008).

CD8[−]CD11b⁺ DCs

In contrast, CD8[−]CD11b⁺ DCs are strictly dependent on RbpJ/CBF1 (recombining binding protein suppressor of hairless), NF κ B, IRF2, and IRF4 transcription factor expression, but also on the presence of Zbtb46 (Satpathy *et al.*, 2012; Suzuki *et al.*, 2004; Caton *et al.*, 2007; Schlitzer *et al.*, 2013; Vander Lugt *et al.*, 2014). CD8[−]CD11b⁺ DCs can be found in the splenic marginal zone and red pulp as well as in the lymphatic zone of the lymph node (Germer *et al.*, 2012; Dudziak *et al.*, 2007). These cells additionally coexpress of CLR, including DCIR2 (mostly in the spleen), which is recognized by the monoclonal antibody 33D1, but also other immunoregulatory molecules such as the molecule signal-regulatory protein alpha (SIRP α /CD172a) (Dudziak *et al.*, 2007; Vremec *et al.*, 2000; Shortman and Liu 2002). CD8[−]CD11b⁺ DCs can be further subdivided into CD4⁺CD8[−]CD11b⁺ and CD4[−]CD8[−]CD11b⁺ DCs. However, subset specific differences have not been clearly defined yet (Vremec *et al.*, 2000).

The direct delivery of antigen using antigen targeting strategies indicates that in contrast to CD8⁺CD11b[−] DCs, CD8[−]CD11b⁺ DCs excel in MHC class II presentation and are superior in presenting endocytosed antigens to CD4⁺ helper T cells (Dudziak *et al.*, 2007; Soares *et al.*, 2007; Pulendran *et al.*, 2008; Yamazaki *et al.*, 2008; Boscardin *et al.*, 2006). This is correlated with an increased expression of molecules important for MHC-II antigen processing, for example, GILT, cathepsins, Legumain, and H2-DM (Dudziak *et al.*, 2007). Recently, it was postulated that IRF4 might be the most important factor not only for the development of CD8[−]CD11b⁺ DCs, but also for controlling the transcriptional program in this DC subset (Vander Lugt *et al.*, 2014). Interestingly, and in line with the differential expression pattern of the two main DC subpopulations, upon antigen engulfment CD8[−]CD11b⁺ DCs rapidly acidify their endosomal/lysosomal compartments, thus allowing for a more rapid proteolytic cleavage of the uptaken antigens and allocation of the peptides for MHC-II presentation. This process is regulated by the recruitment of the small GTPase Rac1 (Rac2 in CD8⁺CD11b[−] DCs), which is directing NOX2 not to the endosomal/lysosomal compartments, but rather to the plasma membrane (Savina *et al.*, 2009).

Antigen presentation by CD8[−]CD11b⁺ DCs demonstrates their ability to especially prime CD4⁺ T cell responses. This is leading to a CD4⁺ T cell derived secretion of the T_H2 cytokines IL4, IL5, and IL13, especially demonstrated in T_H2 prone Balb/c mice (Soares *et al.*, 2007; Maldonado-López *et al.*, 1999). Further, by measurement of the cytokine IFN γ but also by the indirect measurement of IgG subclasses, CD8[−]CD11b⁺ DCs have been demonstrated to be also able to induce CD4⁺ T_H1T cell responses (Do *et al.*, 2010; Soares *et al.*, 2007; Neubert *et al.*, 2014; Boscardin *et al.*, 2006). Interestingly, CD8[−]CD11b⁺ DCs might not directly secrete cytokines themselves. Data indicate that NOTCH ligands (such as DLL4) were found to be specifically generated by CD8[−]CD11b⁺ DCs, thereby enabling this DC subset to generate CD4⁺ T_H1 T cell responses even in the absence of IL12 (Skokos and

Nussenzweig, 2007; Tu *et al.*, 2005; Amsen *et al.*, 2004). Under non-stimulatory conditions the ability of CD8⁺CD11b⁺ DCs has been described to further expand inducible T_{reg} cells, thereby indicating a specific role in the maintenance of peripheral CD4⁺ T cell tolerance (Yamazaki *et al.*, 2008).

Importantly, under specific immunoactivatory conditions, even CD8⁺CD11b⁺ DCs might be capable to present exogenous antigens, for example, antibody immune complexes, for the induction of CD8⁺ T cell responses, as demonstrated by den Haan and Bevan (den Haan and Bevan, 2002). How this is regulated in this DC subset is under current investigation.

Non-Lymphoid Tissue DC

Non-lymphoid tissue and skin DCs display a heterogeneous population characterized by a differential expression of CD11b, CD103, and CD207 (Henri *et al.*, 2010; Malissen *et al.*, 2014). In addition, they exhibit select patterns of TLRs, CLRs, chemokine receptors, and production of distinct cytokines. In the following, we will only provide a brief overview of those DC subsets. Further details can be obtained from excellent reviews by the group of Miriam Merad (Merad *et al.*, 2013; Helft *et al.*, 2010).

CD103⁺CD11b[−] DCs

The integrin α chain (CD103) positive CD103⁺CD11b[−] DCs are phenotypically and transcriptionally similar to lymphoid tissue CD8⁺CD11b[−] DCs as they have the same developmental origin. It was demonstrated that CD103⁺CD11b[−] DCs are also dependent on IRF8, BATF3, and Id2 transcription factors (Ginhoux *et al.*, 2009; Edelson *et al.*, 2010). CD103⁺CD11b[−] DCs can be found at the interface to the environment in intestinal, pancreatic, and pulmonary tissues. They accumulate in Peyer's patches but overall they never reach more than 20–30% of CD11b⁺ DCs (Merad *et al.*, 2013). CD103⁺CD11b[−] DCs coexpress MHC-II, partly Langerin (beside pancreatic and intestinal tissues), CD8 (beside lamina propria tissue) as well as Flt3, but lack macrophage markers such as CD115 (c-kit), CX3CR1, CD11b, or F4/80 (Merad *et al.*, 2013).

Upon antigen encounter CD103⁺CD11b[−] DCs migrate to the T cell zones of draining lymph nodes (Gerner *et al.*, 2012). It was demonstrated that also CD103⁺CD11b[−] DCs, similar to CD8⁺CD11b[−] lymphoid resident DCs, are capable to cross-present antigens to CD8⁺ cytotoxic T cells. This is correlating with the finding that CD103⁺CD11b[−] as well as CD8⁺CD11b[−] DCs coexpress the chemokine receptor XCR1, which interacts with the XCL1 ligand produced by CD8⁺ T cells for the interaction of the antigen presenting DC with the specific T cell. If there are differences between the CD103⁺CD11b[−] and CD8⁺CD11b[−] DCs in the escape of the engulfed antigens, the pH regulation in the endosomal/lysosomal compartments, or the antigen processing machinery is not clear at the moment. As described above in BATF3^{−/−} mice, both CD8⁺CD11b[−] and CD103⁺CD11b[−] DCs are diminished leading to reduced antiviral and antitumor immune responses. However, antibody responses were not abrogated in this mouse model (Hildner *et al.*, 2008; Edelson *et al.*, 2010).

At the moment a specific mouse model to decipher the roles of lymphoid tissue-resident CD8⁺CD11b[−] and non-lymphoid tissue CD103⁺CD11b[−] DCs is not available.

CD11b⁺ DCs

Until today it is still challenging to truly define the function of non-lymphoid tissue CD11b⁺ DCs. They are localized in similar tissues as CD103⁺CD11b[−] DCs, but can be less accurately distinguished from tissue macrophages. This is due to the finding that tissue macrophages also express the surface molecule CD11c. Thereby divergent functional descriptions of CD11b⁺ DCs exist. In muscle CD64 (Fc γ RI) was described to be an excellent marker for the definition of monocyte derived DCs, thereby distinguishing them from tissue CD11b⁺ DCs (Langlet *et al.*, 2012). In the lamina propria CD11b⁺ DCs can be separated into CD11b⁺CD103⁺ and CD11b⁺CD103[−] DCs (Bogunovic *et al.*, 2009; Schulz *et al.*, 2009). CD11b⁺ DCs migrate to the lymph nodes when they have engulfed pathogenic antigens (Gerner *et al.*, 2012). Those migratory DCs (see below) have been described to induce mainly CD4⁺ T cell responses either upon virus infection or antigen encounter in combination with TLR ligation. Further data indicate that non-lymphoid tissue resident CD11b⁺ DCs have also tolerogenic functions as they express aldehyde dehydrogenase (ALDH), which is necessary to metabolize vitamin A into retinoic acid. Retinoic acid is described to be important for the induction of regulatory T cells (Merad *et al.*, 2013; Guillemins *et al.*, 2010). A mouse model in which only non-resident CD11b⁺ DCs are deleted is not available yet.

Langerhans cells and migratory DCs

In the murine skin as a non-lymphoid tissue five different CD11c⁺MHC-II⁺ DC subpopulations have been described so far (Malissen *et al.*, 2014; Merad *et al.*, 2008; Tamoutounour *et al.*, 2013; Mollah *et al.*, 2014; Henri *et al.*, 2010). Beside CD8, CD11b, and CD103, the cell adhesion molecule EpCAM as well as XCR1, CD24, and the C-type lectin receptor Langerin (CD207) are used for a proper subdivision of skin DCs. The skin consists of epidermis, dermis, and subcutaneous tissue. Langerhans cells (CD103[−]EpCAM⁺Langerin⁺) reside in the murine epidermis. In the dermis, beside CD103[−]CD11b⁺EpCAM⁺Langerin⁺ migratory Langerhans cells, four other DC subpopulations can be defined (Pulendran *et al.*, 2008; Romani *et al.*, 2010; Schulz and Steinman, 1985). These are CD103⁺CD11b^{low}EpCAM[−]Langerin⁺ dermal DCs (CD103⁺Langerin⁺ dermal DCs), CD103[−]CD11b^{high}EpCAM[−]Langerin[−] dermal DCs (CD11b⁺ dermal DCs), CD103[−]CD11b^{low}EpCAM[−]Langerin⁺ dermal DCs (CD103[−]Langerin⁺ dermal DCs), CD103[−]CD11b^{low}EpCAM[−]Langerin[−] dermal DCs (CD103[−]Langerin[−] dermal DCs), and CD103[−]CD11b⁺EpCAM⁺Langerin⁺ migratory Langerhans cells (Poulin *et al.*, 2007; Nagao *et al.*, 2009; Stoitzner *et al.*, 2003). Migratory Langerhans cells can also be visualized in skin-draining lymph nodes (Stoitzner *et al.*, 2003). CD103⁺Langerin⁺ dermal DCs can be distinguished from migratory Langerhans cells by their lack of Birbeck granules and the absence of the cell adhesion molecule EpCAM. Also the two Langerin[−]CD103[−]EpCAM[−] dermal DCs lack the formation of Birbeck granules (Merad *et al.*, 2008).

CD11b⁺ dermal DCs have been found to migrate into the interfollicular zone of the draining lymph node (Gerner *et al.*,

2012). Further, dermal and pulmonary migratory CD11b⁺ DCs have been described to efficiently prime CD4⁺ T cell responses upon infection with HSV-1 or influenza virus *ex vivo* (Bedoui *et al.*, 2009; Kim and Braciale, 2009), as well as against *Candida albicans* (Igyártó *et al.*, 2011). These findings are in line with the observation that Langerin⁺ dermal DCs are able to induce CD4⁺ responses, but also regulatory T cell responses, when antigens (either protein or by antigen targeting to Langerin⁺ cells) were injected subcutaneously in combination with an adjuvant (Kastenmüller *et al.*, 2011; Idoyaga *et al.*, 2008). Moreover, CD103⁺Langerin⁺ dermal DCs seem to be related to splenic CD8⁺CD11b⁺ cDCs in regard to their cross-presentation capacity and Th1 CD4⁺ T cell priming potential (Ginhoux *et al.*, 2009; Bedoui *et al.*, 2009). In addition, also CD103[−] dermal DCs were described in murine skin-draining lymph nodes, with the capacity to produce retinoic acid and a subsequent induction of Foxp3⁺ regulatory T cells (Guilliams *et al.*, 2010). Interestingly, the depletion of this DC subset in Langerin-DTR mice abolished the induction of CD4⁺ Th1 responses in a model of autoimmune encephalomyelitis (King *et al.*, 2010). In contrast, although CD8⁺ T cell responses are strongly reduced in this mouse model against *Leishmania major*, CD4⁺ T cell responses were not affected. These findings demonstrate that both the nature of the encountered pathogen and the mouse system used are important for the DC-induced immune response.

Langerhans cells have been described as the most efficient DCs in T cell priming. Overall, Langerhans cells are less efficient than previously thought after the analysis of a variety of mouse models, in which Langerhans cells are depleted. In contact hypersensitivity analyses, evidence was raised that dermal CD103⁺ DCs are able to take over Langerhans cell function (Kaplan *et al.*, 2005; Kaplan, 2010; Edelson *et al.*, 2010). Further, HSV-1 infection of Langerhans cells did not induce an efficient CD8⁺ T cell response, while other dermal DCs did. Interestingly, Langerhans cells might play a role in tolerance induction but also in the induction of Th17 responses induced by *Candida albicans* (Igyártó *et al.*, 2011; Merad *et al.*, 2013).

Functional Specialization in Antigen Presentation of Human DC Subpopulations

Lymphoid Tissue DCs

In contrast to the murine DC system, the picture of human DC subpopulations is rather incomplete. Up to date, most knowledge is obtained from blood DCs or MoDCs (Sallusto and Lanzavecchia, 1994; Shortman and Liu, 2002; MacDonald *et al.*, 2002; Dzionek *et al.*, 2000). However, in recent years insight into the biology of human tissue DCs has steadily increased (Haniiffa *et al.*, 2012; Segura *et al.*, 2012; Segura and Amigorena, 2014; Klechevsky *et al.*, 2008; Paessens *et al.*, 2008; Mittag *et al.*, 2011; McGovern *et al.*, 2014a). Limiting factors are ethical constraints, difficult availability of healthy human organs, and low frequencies of the various human tissue DC subpopulations. For example, human blood DCs account for only 0.16–0.68% of circulating peripheral blood leukocytes (Haller Hasskamp *et al.*, 2005). DCs are commonly referred to as lineage negative (LIN[−]), which discriminates them from

other cell types such as T cells, B cells, NK cells, and erythrocytes by the lack of expression of the cell surface molecules CD3, CD19 and CD20, CD56, and CD235a, respectively (Merad *et al.*, 2013). Further, anti-CD14 and anti-CD16 (FcγRIII) antibodies are frequently included in the lineage cocktail. However, attention has to be paid on the analyzed tissue, since CD14⁺ lymph node and dermis-resident DC subpopulations have been postulated (Segura *et al.*, 2012; Nestle *et al.*, 1994). However, based on phenotypic and transcriptome studies these cells might rather be of monocyte/macrophage origin (Segura *et al.*, 2012; Schlitzer and Ginhoux, 2014). In addition, the existence of a CD16⁺ slanDC population in human peripheral blood and skin has been reported, but is still under debate (MacDonald *et al.*, 2002; Schäkel *et al.*, 2002; Hänsel *et al.*, 2011; Döbel *et al.*, 2013; Cros *et al.*, 2010). Nevertheless, the lineage cocktail composition needs further clarification and tissue-specific refinement.

Efforts have been made to unify the nomenclature of human DC subpopulations (Ziegler-Heitbrock *et al.*, 2010; Guilliams *et al.*, 2014). As a consequence, various alternatives can be found in the literature. Under non-inflammatory conditions two major groups of DC subpopulations (conventional DCs (cDCs) and pDCs), both expressing HLA-DR (human leukocyte antigen DR, the human equivalent to murine MHC-II), have been described in human lymphoid tissues such as blood, spleen, tonsils, lymph nodes, and bone marrow (Merad *et al.*, 2013; Dzionek *et al.*, 2000; McIlroy *et al.*, 2001; Poulin *et al.*, 2010; Mittag *et al.*, 2011; Segura *et al.*, 2013, 2012; Jongbloed *et al.*, 2010; Nizzoli *et al.*, 2013). The phenotype of human DC subpopulations in further lymphoid tissues (e.g., thymus or cord blood) is under current investigation. Conventional DCs contribute two subpopulations. The first, named CD1c⁺ DCs (also referred to as cDC2 DCs, myeloid-derived DCs type 1 (mDC1 DCs), CD11b-like DCs, or BDCA1⁺ DCs), shows high levels of CD1c, SIRPα (CD172a), and CD11c. The second conventional DC subpopulation is represented by CD141⁺ DCs (also called cDC1 DCs, mDC2 DCs, CD8-like DCs, or BDCA3⁺ DCs), which are characterized by the expression of CD141 (BDCA3), Clec9A, XCR1, Nect2, an intermediate level of CD11c, and by the absence of CD1c (BDCA-1), CD14, SIRPα, and CD123 (Merad *et al.*, 2013; Dzionek *et al.*, 2000; Huysamen *et al.*, 2008; McGovern *et al.*, 2014b; Bachem *et al.*, 2010). The third major blood DC subpopulation are plasmacytoid DCs (pDCs), which are CD1c[−] and CD11c^{low}, but can be identified by the expression of CD303 (BDCA2), CD304 (BDCA-4), and CD123 (Merad *et al.*, 2013; Dzionek *et al.*, 2000). As a key feature, pDCs rapidly respond to viral infection by the secretion of type I interferons (Cella *et al.*, 1999). In addition to these three major DC subpopulations, Segura *et al.* have identified three skin-derived migratory DC subpopulations in human axillary lymph nodes, namely migratory Langerhans cells, CD1⁺ DCs, and CD206⁺ DCs (Segura *et al.*, 2012).

The identification of the human functional ortholog of mouse CD8⁺ DCs proved to be challenging due to the lack of CD8 expression on human DCs (Shortman and Liu, 2002). In 2008 and 2010, several research groups independently declared CD141⁺ DCs as the human counterpart of the cross-presenting murine CD8⁺ DC subpopulation (Robbins *et al.*, 2008; Poulin *et al.*, 2010; Bachem *et al.*, 2010; Jongbloed *et al.*, 2010; Crozat *et al.*, 2010). The authors collectively pointed out similarities of mouse CD8⁺ DCs and human CD141⁺ DCs

based on cell surface marker expression (e.g., XCR1, Clec9A (DNCR-1)) and on the superiority of CD141⁺ DCs in the cross-presentation of soluble or cell-associated HCMV protein pp65 or necrotic cell antigens (including viral proteins). Haniffa *et al.* (2012) demonstrated a pronounced capacity of blood CD141⁺ DCs to cross-present soluble hepatitis B surface antigen (HBsAg) after TLR3 specific poly(I:C) stimulation. The assumption that human CD141⁺ DCs are orthologous to murine CD8⁺ DCs gained further support by the description of the transcription factors BATF3 and IRF8, which are expressed in both cell types (Poulin *et al.*, 2010; Hildner *et al.*, 2008). However, in contrast to the mouse system the development of all human DC subpopulations as well as monocytes is abrogated due to a specific IRF8 mutation, which leads to impaired transcriptional activity, suggesting differential pathways in these two species (Hambleton *et al.*, 2011; Segura and Amigorena, 2014).

It was further documented in *in vitro* culture systems that CD141⁺ blood DCs display a superior XCL1-dependent migratory behavior (Bachem *et al.*, 2010; Crozat *et al.*, 2010). In addition, both the murine and the human cell surface molecule Clec9A seem to be responsible for sensing and cross-presentation of dead-cell-associated material *in vitro* and *in vivo* (mouse) via SYK kinase signaling (Sancho *et al.*, 2009; Poulin *et al.*, 2010). Thus, the C-type lectin receptor Clec9A does not seem to be directly involved in the uptake mechanism, but rather in routing endocytosed dead-cell material into non-lysosomal compartments, therefore facilitating cross-presentation (Sancho *et al.*, 2009). Accordingly, it was reported by Crozat *et al.* that the Clec9A expressing human CD141⁺ blood DC subpopulation excels in the cross-presentation ability of apoptotic cell-associated HIV peptides under poly(I:C) stimulated conditions *in vitro* (Crozat *et al.*, 2010).

However, evidence has emerged in recent years that most if not all human DC subpopulations are capable of cross-presenting antigen. Segura and Amigorena have nicely summarized recent findings on the capacity of human blood and lymphoid organ DCs as well as skin DC subpopulations for the cross-presentation of long peptides, soluble antigens, cell-associated antigens, or antigens delivered via receptor targeting (Segura and Amigorena, 2014). Thus, it seems that cross-presentation is not restricted to intrinsic properties of a single DC subpopulation in humans, but is rather dependent on a combination of circumstances. The type of antigen, and thus the uptake mechanism as well as pathogen-intrinsic properties play a role in the route of antigen presentation. For example, *Listeria monocytogenes* produce listeriolysin O (LLO), facilitating lysosomal escape and leading to MHC-I presentation after proteasomal degradation (Cohn *et al.*, 2013). Further data indicate that the kind of stimulatory environment as well as the timing and stage of the immune reaction are decisive for the cross-presentation capacity as summarized by Nierkens *et al.* (Nierkens *et al.*, 2013). Many earlier studies have used poly(I:C) as the stimulatory adjuvant, which favors CD141⁺ DCs due to their high TLR3 expression (Jongbloed *et al.*, 2010). However, more appropriate TLR stimuli resulted in efficient cross-presentation of CMV pp65 protein by blood CD1c⁺ and CD141⁺ DCs (Nizzoli *et al.*, 2013). Of note, a comprehensive analysis of the cross-presentation capacity of the various DC subpopulations from human lymphoid

and non-lymphoid tissues considering different stimuli and administered antigens remains missing. These *in vitro* data can only provide limited insight into human DC cross-presentation, since different contributions of the various human DC subpopulations in the resolution of an infection add more complexity to the topic. Regarding the T helper cell polarization potential accumulating data suggest that CD141⁺ DCs are specialized in the induction of T_H1 T cell responses, whereas CD1c⁺ DCs predominantly elicit T_H2 and T_H17 responses (Schlitzer and Ginhoux, 2014; McGovern *et al.*, 2014a). In contrast, other research groups believe that CD141⁺ DCs mainly induce T_H2 T cell responses, while CD1c⁺ DCs prefer the initiation of T_H1 T cell polarization (Yu *et al.*, 2014). It was further demonstrated that human blood and tonsillar CD1c⁺ DCs exceeded in the production of IL-12 and were highly efficient in cross-presenting soluble CMV pp65 protein under appropriate TLR stimulation in comparison to the corresponding CD141⁺ DC or pDC subpopulations (Nizzoli *et al.*, 2013). In conclusion, further in-depth analyses will have to shed light on the T helper cell polarization potential of human lymphoid (and non-lymphoid) tissue DC subpopulations.

Non-Lymphoid Tissue (NLT) DCs (Skin) and Migratory DCs

In line with murine DCs, human DC subpopulations exhibit sentinel functions not only in the blood and primary lymphoid organs, but also in non-lymphoid tissues. Therefore, human DCs have been described in the lungs, liver, gut, and skin (e.g., Haniffa *et al.*, 2012; Watchmaker *et al.*, 2014; Boltjes and van Wijk, 2014). Romani and colleagues described the skin as the home of epidermal CD1⁺CD207⁺EpCAM⁺ Langerhans cells (with their characteristic Birbeck granules) and dermal Langerin⁺ DCs, ideally positioned to take up antigen for a subsequent presentation to antigen-specific T cells in a skin-draining lymph node. *In vitro* studies have demonstrated that Langerhans cells are capable of initiating T_H1, T_H2, T_H17, and T_H22 CD4⁺ T cell polarization as well as CD8⁺ T cell responses via cross-presentation (Klechevsky, 2013).

Dermal Langerin⁺ DCs can be further subdivided into CD14⁺ and CD1⁺ dermal DCs, of which the latter population harbors CD1c⁺ DCs and CD141⁺ DCs (Romani *et al.*, 2010b; Boltjes and van Wijk, 2014). Skin-derived CD141⁺ DCs were shown to exhibit a superior capacity to cross-present soluble antigens, in comparison to CD1c⁺ DCs (Haniffa *et al.*, 2012). Of note, transcriptomic analyses of dermal CD14⁺ DCs have led to the assumption that these cells are of rather monocytic origin (McGovern *et al.*, 2014a). Under inflammatory conditions, additional DC subpopulations migrate into the skin, such as pDCs, 'Tip-DCs', and inflammatory dendritic epidermal cells (IDEC) (Romani *et al.*, 2010a,b; Boltjes and van Wijk, 2014).

Conclusions

- DCs are important antigen presenting cells
- DCs are key regulators for the induction of immune responses, but also for maintaining peripheral tolerance

- DCs can be stimulated upon recognition of microbial and viral antigens leading to migration, upregulation of co-stimulatory molecules, and antigen processing
- DCs present antigenic peptides as pMHC-I or pMHC-II complexes to CD8⁺ or CD4⁺ T cells
- At least four different ways of antigen processing with (1) classical MHC-I presentation, (2) classical MHC-II presentation, (3) cross-presentation, and (4) autophagy are described
- Cross-presentation is defined as most important processing way for the induction of immune responses against viral and tumor antigens and is tightly regulated
- Variety of DC subsets with differential function in antigen processing and presentation
- Overall, distinction into (1) classical/conventional resident and migratory DCs in lymphoid and non-lymphoid tissues and (2) plasmacytoid DCs
- In the mouse system: CD8⁺CD11b[−] (also CD103⁺) DCs efficient in cross-presentation to CD8⁺ T cells
- In the human system: various reports with different findings on DC subset functions indicating (so far) no specialization of a defined DC subset for cross-presentation.

CD28 Costimulation and Regulatory T Cells

Introduction

An important feature of a mammalian organism is its ability to protect itself against infectious agents such as viruses and bacteria present in the environment. Over millions of years of evolution, a highly specialized system consisting of different cells and molecules that enable immunity against harmful organisms has developed. Simultaneously, this requires mechanisms in order to prevent an immune response developing against host tissue. Innate immune cells like macrophages, are equipped with receptors which can recognize molecules that are not normally present in the mammalian organism (e.g., lipopolysaccharide (LPS) in bacterial walls), minimizing inappropriate activation. The limitation of this response is that it remains unaltered even in the face of repeated infections, responding in the same manner toward any microorganism that contains a particular recognized pattern. On the other hand, cells of the adaptive immune system such as T cells provide specific immunity, which is capable of long-term 'memory' and more vigorous and rapid responses in the case of reinfection. However, T cells recognize peptide fragments derived from proteins, which have a large, but nonetheless limited, range of possible amino acid configurations. Thus, although the nature of an antigen that T cell recognize enables a vigorous response to specific microorganisms, it also provides a constant threat to host tissues that may contain the same or similar amino acid sequences as part of their normal physiology. Therefore, both T cell development and T cell activation are tightly controlled in order to prevent autoimmune diseases, which can result from such recognition.

How Is the Self-Tolerance Established?

The discrimination between host peptides and those derived from the pathogen proteins is not straightforward and presents a major challenge to adaptive immunity. To protect the host tissue from harmful T cell responses, T cells that recognize self-antigens with a high affinity are not released into the immune system. Instead, such cells are deleted during development in the thymus. This clonal deletion of highly self-reactive T cells represents the basis of central tolerance, steering the immune response away from self-antigens. However, although such developmental controls are important for establishing immune tolerance, they are not sufficient and T cells that survive this 'negative selection' are not completely purged of self-reactivity. In addition, not all host proteins in the periphery are expressed in thymus and T cells therefore emerge that can still recognize self-antigens albeit with the lower affinity. Finally, a large number of new harmless proteins are constantly introduced into our system (e.g., through food). In order to prevent unwanted T cell responses to such proteins a set of mechanisms has evolved to control T cell activation.

Central Tolerance

Using their highly variable T cell receptor (TCR), T cells recognize antigens in the context of major histocompatibility complex (MHC). Given that the number of potential antigens far exceeds the number of TCR genes in the human genome, the main problem is how to generate a TCR repertoire broad enough to recognize all conceivable antigens present in our environment (Sewell, 2012). Evolution has solved this problem by introducing random gene rearrangement of TCR genes during T cell development, which drives enormous variability. However, the random nature of the process introduces two major problems. To begin with, the majority of T cells that express randomly rearranged TCRs cannot recognize MHC molecules and are deleted in the thymus with only T cells that can bind to peptide-MHC complex being positively selected. Interestingly, a wide range of tissue-restricted proteins (e.g., insulin) are also processed and presented by thymic antigen-presenting cells (APCs) and T cells that recognize these antigens with high affinity also undergo cell death (negative selection). As such negative selection eliminates the most dangerous T cell clones preventing imminent tissue destruction. Whilst the detailed mechanisms of negative selection are still under investigation it is believed that strong TCR signals generated upon antigen recognition induce pro-apoptotic proteins that mediate cell suicide (Hogquist *et al.*, 2005; Kyewski and Derbinski, 2004).

Negative selection against ectopically expressed self-antigens undoubtedly has a major role in establishing tolerance and mutation in the transcription factor AIRE, which is responsible for driving the expression of tissue-restricted antigens in thymic epithelial cells, leads to a systemic autoimmunity (autoimmune polyendocrine syndrome) (Mathis and Benoist, 2009). However, it is equally clear that despite rigorous selection in the thymus, the peripheral T cell pool still contains T cells capable of reacting to our own tissues, which require additional specific mechanisms of control in a process generically termed peripheral tolerance.

Peripheral Tolerance

Deleting every T cell that can recognize a self-antigen would result in an extremely limited repertoire and most likely would not be compatible with sufficient diversity of pathogen recognition. Therefore, a set of additional mechanisms has been established in the periphery in order to allow the existence of weakly self-reactive T cells that are potentially useful against pathogens (Walker and Abbas, 2002). In the last decade, a variety of molecules implicated in the peripheral regulation of T cell responses have been described. For instance, defects in FoxP3 (a master transcription factor in regulatory T cells), CTLA-4 (a negative regulator of CD28 pathway), TGF- β (T cell growth factor), and IL-10 and IL-2 (anti-inflammatory cytokines) all lead to a severe autoimmunity. Below we discuss in

detail the CD28/CTLA-4 pathway as an essential component of peripheral T cell tolerance.

Responses to pathogens versus responses to self – the role of CD28

Since the T cell repertoire inevitably contains self-reactive T cells, the question arises: how are responses to self-proteins discriminated from the responses to foreign antigens? It is currently thought that activation of CD4⁺ T cells needs at least two signals provided by specialized APCs, such as dendritic cells (DCs), macrophages, and B cells (Figure 1). The first signal is generated when TCR recognizes the antigen displayed by MHC II complex. The requirement for the second signal, known as costimulation, ensures that T cell activation does not occur in the absence of additional information. This is due to the fact that recognition of pathogens (e.g., via Toll-like receptors) or the presence of inflammation specifically upregulates the costimulatory ligands CD80 (B7-1) and CD86 (B7-2) which bind to CD28. Via their interaction with costimulatory receptor CD28, on T cells, these ligands provide signals necessary for a successful T cell activation, proliferation, and differentiation. In this way costimulatory signals are only triggered by the presence of inflammation or 'danger' associated with infection, limiting activation of potentially self-reactive T cells to such settings.

Studies using TCR-transgenic mice that respond to myelin basic protein (MBP), demonstrated that mice housed in standard animal facilities develop experimental autoimmune encephalomyelitis (EAE). In contrast, the same TCR-transgenic mice housed in pathogen-free facilities fail to develop the same disease (Goverman *et al.*, 1993). A simple interpretation of these results is that microbes in the environment are

important in driving the maturation of APCs, enhancing their ability to costimulate. Although these groups of mice have the same TCR specificity, the outcome of immune reaction is dependent on the CD28 engagement. These data along with numerous other studies have firmly established that, CD28 engagement presents a key immune checkpoint that influences self-tolerance: initiating T cell responses not based on the source of peptide antigen, but based on sensing the inflammatory context of recognition. Naturally, regulation of the CD28 pathway then serves as critical point in prevention of autoimmunity.

Regulatory T cells – a specialized cell type that regulate immune responses

Regulatory T cells (Tregs) are a subset of CD4⁺ T cells whose role is to regulate immune responses especially those against self-tissues. This is revealed by diseases such as IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X linked) in humans and the Scurfy phenotype in mice due to loss of Treg function (Bennett *et al.*, 2001; Brunkow *et al.*, 2001). Tregs are characterized by high expression of IL-2 receptor α (CD25) and low level of IL-7 receptor α (CD127). Tregs are generated in thymus upon recognition of self-antigen (called thymus-derived or natural Tregs), or in the periphery upon activation of naïve T cells under tolerogenic conditions (peripherally derived or induced Tregs). The similarities and differences between nTregs and iTregs have been extensively studied and they are reviewed elsewhere (Curotto de Lafaille and Lafaille, 2009; Bilate and Lafaille, 2012).

After discovery of the suppressive activity of Tregs, a major hurdle was how to distinguish them from activated T cells due to the fact that they express high level of CD25, which is

Figure 1 CD28 costimulation controls T cell activation. The goal of T cell activation is to generate a large number of antigen-specific T cells with effector properties that can eliminate pathogens. It is currently thought that activation of CD4⁺ T cells needs at least two signals provided by a specialized APC that captures, processes, and presents antigens as a part of MHC. Simultaneously, recognition of pathogen-related molecules or the presence of inflammation specifically upregulates the costimulatory ligands CD80 and CD86. The first signal is generated when TCR recognizes the antigen displayed by MHC complex. The requirement for the second signal, known as costimulation, ensures that T cell activation does not occur in the absence of additional inflammatory or 'danger' information. Via interaction with CD28, on T cells, CD80 and CD86 provide translate such danger signals to T cells and are therefore necessary for a successful T cell activation, proliferation, and differentiation. The second receptor for the CD80 and CD86 is cytotoxic T lymphocyte antigen 4 (CTLA-4). Expression of CTLA-4 is limited to activated conventional T cells and regulatory T cells (Tregs). CTLA-4 has higher affinity and avidity for both ligands, and serves as a negative regulator of T cell responses.

also upregulated upon the activation of conventional T cells (Tconv). The study of Tregs was therefore greatly facilitated by the discovery of transcription factor FoxP3, which appears to be specific to this lineage (Fontenot *et al.*, 2005). It has been demonstrated that this member of forkhead family of transcription factors is critical for Treg development (Hori *et al.*, 2003; Fontenot *et al.*, 2003). Loss of FoxP3 function causes fatal systemic autoimmune phenotype in both mice and humans characterized by uncontrolled proliferation of T cells, which leads to multiorgan infiltration and failure. Taken together, these studies indicate that Tregs are indispensable for immune homeostasis.

Since the importance of Tregs has been discovered, much work has been performed to elucidate mechanisms by which Tregs regulate immune response. In short, various studies have demonstrated that Tregs can either directly suppress responder T cells, or indirectly modulate the stimulatory capacity of APCs (Shevach, 2009; Josefowicz *et al.*, 2012). Direct mechanisms include production of anti-inflammatory cytokines (e.g., IL-10 or TGF- β), IL-2 consumption, granzyme-mediated apoptosis, and cell-cycle arrest. Of particular interest here is targeting the ability of APCs to provide efficient CD28 costimulation thereby preventing the initiation of T cell response. Evidence from both *in vitro* and *in vivo* experiments shows that Tregs express high levels of CTLA-4 (Takahashi *et al.*, 2000), which is a nonredundant regulator of immune response and is tightly coupled with CD28 costimulation. CTLA-4 appears to be critical for Treg function (Wing *et al.*, 2008; Schmidt *et al.*, 2009) and the molecular basis of this process is described below.

The Biology of the CD28/CTLA-4 Pathway

CD28 is 44 kDa glycoprotein constitutively expressed on the surface of the majority of T cells. It consists of a single extracellular Ig-V-like domain that forms a homodimer. Although other costimulatory pathways have been discovered (e.g., ICOS pathway), CD28 appears to be the apical costimulatory molecule governing T cell activation. As such, mice deficient in CD28 or its ligands CD80 and CD86 show defects in IL-2 production and T cell proliferation, as well as B cell functions such as germinal center formation, antibody levels, and immunoglobulin class switching.

Upon the recognition of CD80 and CD86 ligands, CD28 relocates to the immune synapse where it initiates various costimulatory signaling events (Figure 1). The exact pathways involved in the signal transduction are still under investigation. To date the importance of various kinases in CD28 signaling has been demonstrated, such as PI3K, ITK, Lck, and PKC- θ (Rudd *et al.*, 2009). These molecules initiate a signaling cascade responsible for the activation of genes involved in survival and cell-cycle progression. However, the outcome and the importance of specific signaling pathways initiated upon CD28 engagement remains controversial. Recent data have indicated that CD28 costimulation may be important in actin reorganization within the T cells in order to facilitate activation signals, in a manner that may not be compensated by simply increasing TCR signals (Tan *et al.*, 2014; Dustin and Davis, 2014).

Functions of CD28

It is still unclear whether CD28 engagement causes unique changes in T cell signaling or simply amplifies TCR-based signals. Over years it has been established that costimulation serves to lower the threshold necessary to achieve the activation of T cells, particularly enabling responses to weak agonist TCR ligands. Data indicate that CD28 engagement ensures more rapid division and enhances production of different cytokines, particularly a T cell growth factor IL-2. In addition, it was demonstrated that CD28 increases the expression of the anti-apoptotic protein BCL-X_L thus promoting the survival of T cells (Acuto and Michel, 2003).

Furthermore, it has been suggested that CD28 signaling influences T cell differentiation. The most prominent defect in CD28 knockout mice is the lack of germinal centers and consequently the production of high-affinity antibodies is impaired (Ferguson *et al.*, 1996; Shahinian *et al.*, 1993). This could be due to an indispensable role of CD28 in driving inducible T cell costimulator (ICOS) upregulation that is necessary for the development of follicular helper T cell (Linterman *et al.*, 2009). Moreover, there are indications that high-CD28 signaling in the context of weak-TCR signals drives the production of Th2 cytokines (Lenschow *et al.*, 1996; Smeets *et al.*, 2012), although CD28 does not seem to be absolutely required for Th2 differentiation (Brown *et al.*, 1996).

In addition to its role in conventional T cell activation, studies in CD28 knockout mice revealed that CD28 is also implicated in the generation and homeostasis of thymic regulatory T cells (Sansom and Walker, 2006). Surprisingly, it has been shown that CD28 is required for Treg generation in thymus independently of its role to stimulate IL-2 production. In addition, Gogishvili *et al.* (2013) have shown that CD28 deletion significantly lowered the number of Tregs, but not of conventional T cells in the periphery. More importantly, they showed that IL-2 is not able to compensate for the role of CD28 costimulation in maintaining the number of Tregs in the periphery. Therefore, it appears that in addition to IL-2, there is a nonredundant cell-intrinsic role of CD28 costimulation in peripheral Treg homeostasis (Sansom and Walker, 2013). A recent study showed slightly different results using a Treg-specific CD28 KO mice system (Zhang *et al.*, 2013). Here, except in the thymus, the number of Tregs was fairly well preserved, however, their function was notably impaired. These Tregs had a significantly decreased expression of CTLA-4 and PD-1, leading to a robust autoimmune phenotype.

Although a role for CD28 in Treg selection in the thymus is clear, the role of CD28 in peripheral Treg induction is still controversial. It has been reported that CD28 signaling negatively regulates differentiation of induced Tregs (Semple *et al.*, 2011). However, others have shown that CD28 promotes differentiation of induced Tregs (Gabrysova *et al.*, 2011). Thus, it is likely that the role of CD28 in Treg generation depends greatly on the other signals that T cell receives, particularly the strength of TCR, as well the cytokine milieu in which the activation occurs.

Overall, the CD28 pathway is critical for T cells activation, differentiation, and function. Moreover, given that T cells interact with a number of immune cell types, regulation of

CD28 pathway is therefore crucial for successful B cell, macrophage, and cytotoxic T cell responses. This places CD28/CTLA-4 pathway at the heart of immune regulation.

CTLA-4 – A Key Negative Regulator of T cell Activation

The second receptor for the CD80 and CD86 is cytotoxic T lymphocyte antigen 4 (CTLA-4) (Figure 1). CTLA-4 is 34 kDa type 1 transmembrane glycoprotein expressed by T cells. Genes for CD28 and CTLA-4 are both located on the same region of the chromosome and they share around 30% of homology at the amino acid level indicating that CD28 and CTLA-4 have evolved from the same ancestral gene. Nonetheless, CD28 and CTLA-4 proteins have a very different expression pattern, biological properties, and effects upon T cell responses. Whereas CD28 is constitutively expressed on the surface of most T cells, CTLA-4 expression is limited to activated conventional T cells and more importantly, Tregs. Upon T cell activation, CTLA-4 is synthesized and directed toward the cell membrane, where it binds to CD80 and CD86 with a higher affinity than CD28. Also unlike CD28, CTLA-4 is a highly

endocytic molecule and the amount of time in which it is resident on the cell surface is very limited (Figure 2).

Whereas CD28 engagement promotes T cell activation, CTLA-4 serves as a negative regulator of T cell responses. The importance of CTLA-4 has been widely demonstrated in CTLA-4 KO mice (Tivol *et al.*, 1995) and recently in humans with heterozygous nonsense/missense CTLA-4 mutations (Schubert *et al.*, 2014). T cells from CTLA-4 KO mice exhibit a strong response to self-antigens, which leads to lymphoproliferative disease and these mice die after 3–4 weeks of age from multiorgan failure. In addition, various polymorphisms in CTLA-4 gene have been implicated in different autoimmune diseases in humans (Gough *et al.*, 2005). These phenotypes provide strong evidence that CTLA-4 evolved to prevent autoimmunity, however, the molecular mechanisms used to achieve this have been controversial.

CTLA-4 and CD28 Bind Same Ligands with Different Affinities

CD80 and CD86 are ligands for CD28 and CTLA-4 and both expressed by APCs (Figure 1). CD28 and CTLA-4 are both dimers and they share a conserved MYPPPY amino acid motif that forms the ligand binding domain (Yu *et al.*, 2011).

Figure 2 Cell biology of CTLA-4. CTLA-4 is synthesized on endoplasmic reticulum and matures in Golgi forming the functional homodimer. Upon T cell activation vesicles containing CTLA-4 proteins are targeted toward cell membrane. At the cell surface a YVKM motif in the cytoplasmic domain of CTLA-4 is recognized by the clathrin adaptor protein AP-2 leading to a rapid clathrin-mediated endocytosis. Following internalization, CTLA-4 either recycles back to the cell surface or is degraded in lysosomes. Therefore, CTLA-4 is a highly dynamic protein with short half-life, which recycles and is rapidly degraded in lysosomes.

Importantly, CTLA-4 has higher affinity and avidity for both ligands, which allows CTLA-4 to out-compete CD28 for CD80/86 binding. Thus it has been proposed that CTLA-4 can act by trapping CD80 and CD86 and preventing their interactions with CD28 (Walker and Sansom, 2011).

Surprisingly, although CD80 and CD86 share the same receptors, these two ligands have only around 25% of identity at the protein level. In addition, CD80 exists as a dimer while CD86 appears to be a monomer (Collins *et al.*, 2002). Based on chromosomal location it seems likely that CD80 and CD86 have evolved from the same ancestral gene probably in the process of gene duplication (Zhu *et al.*, 2014), and then acquired specific functions. However, the precise functional differences between CD80 and CD86 are not yet understood.

In terms of interaction with their receptors, CD80 has a significantly higher affinities and avidities for both CD28 and CTLA-4 than CD86, thus suggesting that CD80 is a more potent ligand (Collins *et al.*, 2002). However, studies in CD80 and CD86 knockout mice have revealed that CD86 is more important in T cell activation than CD80 (Borriello *et al.*, 1997). The biology behind the superior capacity of CD86 to costimulate is still unclear and further studies are required to distinguish between effects of expression level and those of affinity and structure. More importantly these results raise another question: if CD86 alone is sufficient to costimulate what is then the role of CD80 in T cell differentiation and function? A more comprehensive understanding of exact roles of CD80 and CD86 during different phases of immune response is awaited and will almost certainly increase our knowledge of T cell biology and enable a more efficient use of immunomodulatory drugs that target CD28/CTLA-4 pathway.

How Does CTLA-4 Function?

The autoimmune phenotype in CTLA-4 deficient mice can be prevented by blocking CD80 and CD86 with CTLA4-Ig (Tivol *et al.*, 1997) or by crossing CTLA-4 KO mice with mice deficient for both ligands (Mandelbrot *et al.*, 1999). This clearly demonstrates that CTLA-4 functions as a regulator of CD28 signaling. Accordingly, CD28 independent T cell activation is not controllable by CTLA-4.

The Mechanism of CTLA-4-Mediated Suppression Is Cell-Extrinsic

Numerous studies in CTLA-4 biology have suggested that upon ligation CTLA-4 delivers negative signal (Rudd *et al.*, 2009) by recruiting protein phosphatases PP2A and SYP to TCR complex, which inhibit TCR signaling by turning off T cell activation and IL-2 production. Other studies have shown that CTLA-4 recruits PI3K or competes with CD28 for PKC θ binding. However, there is still debate as to whether CTLA-4 delivers an inhibitory signal, particularly *in vivo*. To begin with, the idea of negative signaling was predominantly based on experiments using agonistic anti-CTLA-4 antibody, however, there is no natural ligand that solely binds CTLA-4 but not CD28, making such reagents

questionable. Moreover, the precise signaling mechanisms still remain unclear, for example, it has been shown that the interaction of CTLA-4 with PP2A is not necessary for the inhibition of T cell responses (Teff *et al.*, 2009). Other pathways proposed to be initiated by CTLA-4 (i.e., PI3K and PKC θ pathway) are also implicated in CD28 signaling and generally are thought to have positive effect upon T cell activation. The fact that CTLA-4 is not well expressed on the cell surface and possesses a highly dynamic trafficking itinerary (see Section Cell biology of CTLA-4), that limits amount of time in which it is expressed on cell surface is also not easily reconciled with a signaling function (Qureshi *et al.*, 2012).

The most persuasive argument to consider mechanisms other than intrinsic inhibitory signals comes from *in vivo* experiments with chimeric mice. These mice contain both CTLA-4^{+/+} and CTLA-4^{-/-} T cells and have challenged the cell-intrinsic view of CTLA-4 function. Unlike CTLA-4^{-/-} mice that die from lymphoproliferative disease, mice containing both CTLA-4^{-/-} and CTLA-4^{+/+} cells fail to develop this pathology (Bachmann *et al.*, 1999). The most likely explanation for this finding is that CTLA-4^{+/+} cells are able to control expansion and effector functions of CTLA-4^{-/-} T cells. This led to the suggestion that CTLA-4 dominantly suppresses T cell activation via modifying phenotype and function of other cell types such as APCs, consistent with a function on a ‘suppressor’ cell such as a Treg. Until recently a molecular mechanism by which CTLA-4 can control T cell activation in cell-extrinsic manner has been difficult to elucidate (Walker and Sansom, 2011). However, we recently found that CTLA-4 was capable of carrying out a novel cellular process we term transendocytosis (Soskic *et al.*, 2014; Qureshi *et al.*, 2011).

Transendocytosis: A Molecular Mechanism of CTLA-4 Function

From a cell biology perspective, the most fundamental feature of the CTLA-4 protein is its highly endocytic nature (Figure 2). This is somewhat surprising giving that CTLA-4 operates on the cell surface by interacting with CD80 and CD86 expressed on APCs. However, the endocytic behavior of CTLA-4 appears to be crucial for CTLA-4 function. Here we explore cell biology of CTLA-4 and how endocytosis is employed as an effector pathway in order to control T cell responses.

Cell biology of CTLA-4

Upon TCR engagement, the level of CTLA-4 is rapidly increased (Egen and Allison, 2002) and vesicles containing CTLA-4 proteins are targeted toward immune synapse in ADP-ribosylation factor 1 (ARF1) and phospholipase D (PLD) dependant fashion (Mead *et al.*, 2005). At the cell surface, a YVKM motif in the cytoplasmic domain of CTLA-4 is recognized by the clathrin adaptor protein AP-2 leading to a rapid clathrin-mediated endocytosis (Shiratori *et al.*, 1997). Earlier studies have proposed that upon activation tyrosine in YVKM motif is phosphorylated, preventing binding of AP-2 (Shiratori *et al.*, 1997). This would cause stabilization of CTLA-4 at the cell surface. Although evidence exists that *in vitro* phosphorylation of CTLA-4 or overexpression of Src kinase prevents AP-2 binding (Follows *et al.*, 2001; Chuang *et al.*, 1999), it is

unclear whether this happens under physiological stimulation. Indeed our group has found that clathrin-mediated endocytosis generally persists during T cell activation, and at any given time approximately 90% of CTLA-4 molecules are expressed intracellularly (Qureshi *et al.*, 2012). Therefore the increase of CTLA-4 at the cell surface following T cell activation is not due to the disruption of CTLA-4 internalization, but rather to the increased delivery of CTLA-4 containing vesicles to the cell surface resulting from the increased protein levels during T cell activation.

Upon internalization, the fate of CTLA-4 is still rather unclear. Our lab has demonstrated that CTLA-4 co-localize with Rab11 (Qureshi *et al.*, 2012), which is known to regulate recycling of endocytosed proteins and there is evidence that CTLA-4 can recycle back to the cell surface. Further precise studies are still required to elucidate motifs and molecular mechanisms involved in CTLA-4 recycling. Multiple studies have also shown that CTLA-4 is degraded in lysosomal compartments and neutralization of lysosomal pH using ammonium chloride (NH_4Cl) increases the expression of CTLA-4 (Kaur *et al.*, 2013; Egen and Allison, 2002). On the other hand, blocking protein synthesis with cycloheximide (CHX) results in the rapid decrease of CTLA-4 level giving a half-life of CTLA-4 of around 2 h (Egen and Allison, 2002). The above data provide evidence that CTLA-4 is a highly dynamic protein with short half-life, which recycles and is rapidly degraded in lysosomes. Understanding the cell biology of CTLA-4 in the context of its function is therefore clearly important (Figure 2).

Overall, although CTLA-4 shares the same ligands with CD28 it has strikingly different biology. The highly dynamic nature of CTLA-4 has presented a major conundrum in the field. Interestingly, it has been shown that cytoplasmic domain of CTLA-4 is highly conserved among all mammals, suggesting that there is a strong evolutionary pressure to maintain a complex CTLA-4 trafficking across species (Walker and Sansom, 2011). We have therefore taken the view that CTLA-4 trafficking is key to its function.

Transendocytosis: cell biology at the heart of immune regulation

In recent studies we have observed that CTLA-4 effectively can act as a molecular Hoover that removes CD80 and CD86 ligands from the surface of APCs, by ‘transendocytosis’ (Qureshi *et al.*, 2011; Figure 3). By depleting ligands, CTLA-4 reduces the capacity of APCs to provide effective costimulation through CD28, thereby directly coupling the function of CTLA-4 to CD28 as observed in *in vivo* experiments. To elucidate the mechanism of CTLA-4-mediated depletion of ligands, we have generated cell lines that expressed CTLA-4 and CD80 or CD86 tagged with green fluorescent protein (GFP) (Figure 4). Perhaps most strikingly, we have observed that the entire receptor–ligand complex (including cytoplasmic domain of ligands tagged with GFP) gets internalized into CTLA-4 expressing cell. The complex is subsequently targeted to lysosomes where ligands are rapidly degraded while CTLA-4 may recycle back to the cell surface to capture more ligands (Figure 3). This latter point still requires more research but it is clear that ligands are degraded and that this is inhibited by agents such as NH_4Cl . Further, to test the relevance of transendocytosis *in vivo* we generated mice that express CD86-GFP on the surface of their APCs. Strikingly, capture

Figure 3 Transendocytosis – A molecular mechanism of CTLA-4 action. Upon activation CTLA-4 containing vesicles are targeted to the immune synapse (the site of T cell–APC interaction), where it binds CD80 or CD86. Subsequently, the entire receptor–ligand complex gets internalized into T cell. The process of CTLA-4 dependent CD80/86 internalization is termed transendocytosis. The complex is targeted to lysosomes where ligands are rapidly degraded while CTLA-4 may recycle back to the cell surface to capture more ligands. As such CTLA-4 expressed by Tregs can remove ligands from APC preventing the activation of all T cells that subsequently recognize antigens presented by that APC. This provides an efficient mechanism of immune suppression and controls the level of CD80 and CD86 expression.

of ligands was observed only in $\text{CD}4^+ \text{CD}25^+$ T cells (activated conventional T cells or Tregs) and $\text{CD}4^+ \text{CD}25^+$ T cells from $\text{CTLA-4}^{-/-}$ mice did not acquire ligands demonstrating that the transfer of ligand is CTLA-4 dependent *in vivo*. More importantly, the transendocytosis occurred only upon peptide stimulation indicating that the process is antigen specific. These features are highly consistent with a role for CTLA-4 on regulatory T cells as an effector mechanism for reducing costimulation via CD28.

Although the exact molecular players involved in CTLA-4 transendocytosis are currently unknown, the concept of intercellular exchange of membrane proteins has been observed elsewhere. A number of studies have shown that various cell types are capable of exchanging their membrane proteins via transendocytosis (Rechavi *et al.*, 2009). A well-characterized example is Notch, which upon the interaction with its ligands is cleaved and internalized into the ligand-expressing cell (Klug and Muskavitch, 1999). This process is necessary to initiate Notch receptor signaling which is implicated in cell differentiation during development. Several other examples of

Figure 4 Confocal microscopy of transendocytosis. Chinese hamster ovary (CHO) cells stably expressing CD86-GFP (green) or CTLA-4 (red) were co-incubated for 8 h. In areas of the coculture where CTLA4-expressing cells are absent (a) CD86-GFP is preserved at the plasma membrane. However, where ligand-expressing cells make close contact with CTLA-4 expressing cells CD86 ligand is taken up by the CTLA4-expressing cells and destroyed. Accordingly most of the GFP signal is lost (b). In the presence of lysosomal inhibitor NH₄Cl (c) the degradation of CD86-GFP is blocked and the captured ligand accumulates in intracellular vesicles within the CTLA4-expressing cells.

transendocytosis have been described, including the bi-directional transfer of CD47–SHPS-1 complex (Kusakari *et al.*, 2008), which controls T cell activation, and transendocytosis of ephrin B that regulates contact repulsion (Marston *et al.*, 2003). While transendocytosis involves transfer of ligands directly into receptor-expressing cell, it has some distinctions from similar processes such as Trogocytosis (Daubeuf *et al.*, 2010) which is common in the immune system (Davis, 2007). It has been identified that within the minutes of co-incubation of NK cells with their targets, NK cell receptor KIR is transferred to target cell in MHC I dependent fashion by trogocytosis. Similarly, several studies have shown that CD4⁺ T cells can acquire MHC II, CD80, and CD86 from APCs. Interestingly, CD28-expressing cells can also acquire CD80 and CD86 ligands, however, CD28-mediated transfer is by trogocytosis. In our experience whilst trogocytosed proteins remain detectable on the cell surface after transfer, in transendocytosis transferred proteins are directly routed to an intracellular compartment, which precludes surface detection.

Transendocytosis as a mechanism of immune regulation

A long-term conundrum in immunology has been why a key stimulatory protein (CD28) and a key inhibitory molecule (CTLA-4) would share the same ligands. If CTLA-4 is viewed as a receptor that delivers negative signal, then it is difficult to imagine the evolutionary logic behind controlling activation and inhibition of T cell responses with the same triggers. However, from transendocytosis perspective the core concept behind the model is that CTLA-4 must share the ligands with CD28 in order to function. Furthermore, in order for suppression to be efficient, CTLA-4 needs to be able to compete with CD28 for CD80 and CD86 binding, which is in agreement with biophysical characteristics of interaction between

CD28/CTLA-4 and its ligands. The transendocytosis model therefore describes a form of competition between CD28 and CTLA-4 that is cell-extrinsic and where competition between CD28 and CTLA-4 can be temporally separated. As such CTLA-4 expressed by Tregs can remove ligands from APC preventing the activation of all T cells that subsequently recognize antigens presented by the same APC.

In transendocytosis, the ability of CTLA-4 to internalize CD80 and CD86 from APC membrane is dependent on both the number of ligands that are expressed by APC and number of CTLA-4 molecules. Therefore a key feature of CTLA-4-mediated immune control is that it is quantitative. As such, if the inflammatory environment (i.e., due to the presence of pathogen) drives increased expression of ligands, CTLA-4-mediated suppression has a diminished efficacy. In these settings, if the production of CD80/86 is greater than their downregulation, this allows the engagement with CD28. On the other hand, if the level of CD80/86 ligands is lower, CTLA-4 can act to keep the level below the threshold necessary for costimulation, thus preventing the activation of self-reactive T cells.

CTLA-4: a key mechanism of Treg suppression

Numerous studies have suggested that CTLA-4 plays a major role in Treg-mediated suppression of immune response (Wing *et al.*, 2008; Schmidt *et al.*, 2009; Onishi *et al.*, 2008). Indeed, there is a remarkable similarity between CTLA-4 KO and Scurfy mice, suggesting that the Scurfy phenotype seen in FoxP3 deficient mice is at least partially a result of the loss of CTLA-4 due to absence of Tregs. Furthermore, removal of CD28 or injection of CTLA4-Ig significantly improves survival of Scurfy mice (Singh *et al.*, 2007).

Transendocytosis offers a simple explanation for CTLA-4 dependent Treg function. Upon the antigen recognition, the

Figure 5 Manipulation of CD28/CTLA-4 pathway. Multiple therapeutic compounds have been designed to manipulate the CD28/CTLA-4 pathway. CTLA4-Ig binds to CD80 and CD86 expressed on APCs preventing their interaction with CD28 and therefore the initiation of T cell responses. CTLA4-Ig is clinically available in two forms: Abatacept and Belatacept. Compared to Abatacept, Belatacept has an increased affinity for CD80 and CD86, with an increased bias toward CD86 blockade. Both these compounds are used as immunosuppressive drugs. As an alternative approach to ligand blockade, CD28-blocking antibodies have been developed for induction of transplantation tolerance and treatment of autoimmunity. In contrast, CD28 superagonistic antibodies have been used to induce immune tolerance by preferential expansion of FoxP3⁺ Tregs. Several CTLA-4-blocking antibodies have also been developed and demonstrated antitumor effects. Thus the system is capable of being manipulated to promote immune tolerance or immune activation depending on the components that are targeted.

expression level and cycling of CTLA-4 dramatically increases in regulatory T cells. As functional consequence, CTLA-4 removes CD80 and CD86 ligands from the surface of APCs and efficiently prevents the activation of self-reactive T cells. In line with this, several studies have demonstrated that Tregs downregulate CD80 and CD86 from APCs in CTLA-4 dependent fashion (Oderup *et al.*, 2006; Onishi *et al.*, 2008; Wing *et al.*, 2008).

Another important concept that arises from this model is that any T cell that expresses CTLA-4 (activated conventional T cells and Tregs) has regulatory capacity (Corse and Allison, 2012; Wang *et al.*, 2012). Indeed it was recently demonstrated that the combination of CTLA-4 expression and IL-2 suppression is sufficient to convert conventional T cells into regulatory T cells with potent immunoregulatory capacity (Yamaguchi *et al.*, 2013).

Manipulation of CD28/CTLA-4 Pathway: Antagonist, Agonists, and Superagonists

The last decade of research in immunology has taught us that the relationship between CD80- and CD86-CD28-CTLA-4 is

extremely well balanced and any disturbance may have a profound influence on the control of the immune response. Because of its central importance, several approaches have been used to manipulate T cell activation through CD28/CTLA-4 pathway (Figure 5).

Blocking CD80 and CD86 is widely used as a strategy for blocking CD28/CTLA-4 pathway. The higher affinity of CTLA-4 for its ligands led to development of CTLA4-Ig fusion protein as an inhibitor of T cell responses. CTLA4-Ig binds to CD80 and CD86 expressed on APCs preventing their interaction with CD28 and accordingly the initiation of T cell responses. CTLA4-Ig is clinically available in two forms: Abatacept and Belatacept. Abatacept has been approved for the treatment of rheumatoid arthritis in patients who failed to respond to antitumor necrosis factor (TNF) therapy (Genovese *et al.*, 2012) and polyarticular juvenile idiopathic arthritis (Goldzweig and Hashkes, 2011). However, a significant proportion of patients do not respond to Abatacept treatment leading to a second generation of artificially engineered CTLA4-Ig variant, LEA29Y (Belatacept). Two amino acid substitutions in Abatacept sequence increases the affinity for CD80 and CD86 with an increased bias toward CD86 blockade. Belatacept has now been approved for clinical use as an immunosuppressant

following kidney transplantation (Gardner *et al.*, 2014; Melvin *et al.*, 2012). Given the above discussions, it is interesting to reflect that removal of ligands by transendocytosis and blocking of ligands with Abatacept may ultimately be functionally equivalent strategies.

Although ligand blockade has been widely accepted as a strategy for manipulating T cell responses, there are several issues that remain to be addressed. To begin with, it is widely appreciated that CD28 costimulation is necessary for generation and homeostasis of regulatory T cells. As such, reducing the number of Tregs by ligand blockade in patients with autoimmunity can be counter-productive. Therefore the impact on both Tregs and effector T cells may be significant for the outcome of the therapy. Another important issue is that CTLA4-Ig can only inhibit CD28-dependent responses and it is still unclear why some T cell responses appear to be less dependent on CD28 signaling (Gardner *et al.*, 2014). As an alternative approach to ligand blockade CD28-blocking antibodies have been developed for induction of transplantation tolerance and treatment of autoimmunity (Poirier *et al.*, 2012). The major challenge of using CD28 antibodies to suppress T cell activation is avoiding potential agonistic effects (Gardner *et al.*, 2014), since CD28 agonists have had a somewhat chequered history. Initially, CD28 superagonistic antibodies were shown to induce immune tolerance by preferential expansion of FoxP3⁺ Tregs in humanized mouse model of graft-versus-host disease (Kitazawa *et al.*, 2009). This data along with numerous other studies have suggested that CD28 superagonistic antibodies may specifically target Treg cells *in vivo* and maintain their suppressive function. However in humans, CD28 superagonistic antibody (TGN1412) caused the rapid release of cytokines from effector memory T cells leading to multiorgan failure (Hunig, 2012). Despite this major setback, recent data again indicates that the selective expansion of Tregs may be possible by low dose of CD28 agonists (Tabares *et al.*, 2014).

Several CTLA-4-blocking antibodies have also been developed and efficacy as antitumor therapies has been tested with remarkable success. Here, the concept is that by blocking natural tolerance mechanisms to our own tissues it may be possible to unleash the immune system against tumors. Ipilimumab, which is the leading CTLA-4 antibody in its class, appears to be effective in treatment of melanoma with a small subset of patients demonstrating remarkable responses. Further understanding of the role of CTLA-4 on both Tregs and activated T cells in response to treatment will almost certainly lead to advancement of anti-CTLA-4 therapy (Callahan *et al.*, 2010). The development of this CTLA-4 blockade approach has now pioneered the rapid development of several tumor immunotherapy approaches (Pardoll, 2012).

Conclusions

- CD28 signaling is essential for T cells activation, differentiation, and function. Moreover, given that T cells interact with a number of immune cell types, CD28 appears to be an apical control point for successful B cell, macrophage, and cytotoxic T cell responses.

- CTLA-4 functions as a direct regulator of CD28 signaling.
- CD28 and CTLA-4 bind the same ligands CD80 and CD86; CTLA-4 has higher affinity and avidity for both ligands.
- CTLA-4 is a highly endocytic protein and has a complex recycling behavior.
- CTLA-4 effectively can act as a 'molecular hoover' that removes CD80 and CD86 ligands from the surface of APCs, by 'transendocytosis.' By depleting ligands, CTLA-4 reduces the capacity of APCs to provide effective costimulation through CD28 and maintains immune tolerance.

Introduction to Stromal Cells

Originally described as noncancerous cells within a tumor, stromal cells are now typically defined as connective tissue cells of an organ. Stroma is comprised of the extracellular matrix and a number of cell types, including mesenchymal cells such as fibroblasts and pericytes, as well as endothelial cells. Stromal cells provide structural support for organs, producing extracellular matrix proteins and basement membrane components. Increasingly, their important role in actively regulating organ homeostasis and function is now becoming better known and in this article we will review the roles of stromal cells in regulating the immune system in both lymphoid and non-lymphoid tissues.

Stromal Cell Regulation of Lymphoid Tissue Structure and Function

Structure of Secondary Lymphoid Organs

Secondary lymphoid organs (SLOs) form a functionally diverse network of tissues that survey the lymph and blood for evidence of foreign organisms in need of clearance from the body. While the spleen and lymph node (LN) are the best studied SLOs, other lymphoid structures such as Peyer's patches, gut- and nasal-associated lymphoid tissues and tertiary lymphoid tissues (TLOs) have similar structures. For the purposes of this article we will focus on the LN, although the stromal cells of the splenic white pulp are essentially functionally equivalent to that present in the LN.

LNs are situated throughout the body, scanning the lymph for pathogens as the lymph drains to be returned to the blood stream. LNs are also encapsulated, and can be divided into three distinct areas: the subcapsular sinus (SCS), cortex and medulla. The SCS is lined with macrophages, which capture antigens and particles that enter the LN via the lymph. The cortex is divided into the outer and para cortex; the former contains the B cell follicles and the latter the T cell zone. Within the T cell zone, specialized blood vessels called high endothelial venules (HEVs) mediate lymphocyte entry into the LN. The lymphocytes, depending on their identity as T or B cells, then localize to the T cell zone, which also contains antigen-presenting dendritic cells (DCs), or to the B cell zone, which contains follicular dendritic cells (FDCs), which have an antigen-presenting function. The localization of lymphocytes in the LN and spleen is controlled by chemokines produced by distinct stromal cell types that populate each area.

Stromal Cells in SLOs

Multiple stromal cell types control the localization of immune cells within SLOs. There are several distinct stromal cell types

within the LN, including endothelial and mesenchymal cells. Endothelial cells line the blood (BEC) and lymphatic (LEC) vessels and not only control the flow of blood and lymph through the LN, but also mediate entry and exit of lymphocytes into the LN. There are five types of mesenchymal stromal cells that populate the LN, which have distinct roles in regulating LN structure and function, but are likely to share a common origin ([Castagnaro et al., 2013](#)). Within the T cell zone, the fibroblastic reticular cells (FRCs) form a dense network of stromal cells that direct the migration of T cells and DCs through interactions between CC chemokine ligand (CCL)19 and CCL21, produced by FRCs, and CC chemokine receptor (CCR)7, expressed on T cells and DCs ([Bajenoff et al., 2006](#); [Forster et al., 1999](#); [Link et al., 2007](#)). FRCs produce interleukin (IL)-7, and thus serve as an important source of T cell survival factors ([Link et al., 2007](#)), and surround and form an important conduit network that shuttles antigens, chemokines and other small molecules through the LN ([Sixt et al., 2005](#)). In the B cell follicle, the FDCs form an intricate stromal network that attracts and retains CXC chemokine receptor (CXCR)5-expressing B cells through expression of CXC chemokine ligand (CXCL)13, and captures and presents antigens and immune complexes during an immune reaction ([Allen and Cyster, 2008](#)). Marginal reticular cells (MRCs) line the SCS and are closely associated with FDCs. Until recently, their function was not well understood but they are now thought to be a precursor for FDCs in the LN ([Jarjour et al., 2014](#)). Lastly, stromal cells called double-negative cells (DNCs) have been described in the LN, so named because they express neither gp38 nor CD31. Among these cells is a population of stromal cells that expresses integrin alpha 7 (ITGA7). These DNCs are closely associated with HEVs, sitting between the BECs and FRCs, and have contractile properties that define them as pericyte-like cells ([Malhotra et al., 2012](#); [Figure 1](#)).

Stromal Cell Regulation of Lymphocyte Migration

The control of lymphocyte and DC migration in LNs is critical to the capacity of the immune system to survey for infection and generate immune responses required for pathogen clearance. Lymphocytes traffic between lymph nodes using the blood and lymph ([Girard et al., 2012](#)). Lymphocytes typically enter LNs via the blood at HEVs. Through the expression of CD62L ligands (in particular glycosylation-dependent cell adhesion molecule-1, GlyCAM-1) and CCL21, HEVs encourage lymphocyte rolling, adhesion and transmigration of CD62L- and CCR7-expressing lymphocytes, resulting in their recruitment into the LN. After entry into the LN, T and B cells then localize to their specific regions, directed by the stromal components therein: FRCs make CCL19 and 21 and thus retain T cells and DCs ([Link et al., 2007](#)); FDCs produce

Figure 1 Stromal cells control the structure of lymphoid tissues. Lymph nodes (LNs) are situated throughout the body and filter the lymph as it drains from peripheral tissues. LNs are critical structures for the maintenance of T and B cells and the generation of immune responses. T and B cells enter the LN from the blood through specialized blood vessels called high endothelial venules (HEVs). The blood endothelial cells (BECs, yellow) of the HEVs express the chemokine CCL21 and various adhesion molecules that promote lymphocyte adhesion, rolling, and transmigration into the LN. Once inside the LN, T cells and B cells localized to specific regions, guided by the stromal cells therein. The T cell zone retains T cells and dendritic cells (DCs), and is populated by the mesenchymal stromal cell, the fibroblastic reticular cell (FRC, blue). FRCs produce CCL19 and CCL21 to attract CCR7-expressing T cells and DCs and T cell survival factors such as IL-7; secrete extracellular matrix components that are the scaffold of the T cell zone; and form conduit networks that shuttle small molecules through the LN. CXCR5-expressing B cells localize to the B cell follicle, attracted by the chemokine CXCL13, which is produced by the follicular dendritic cells (FDCs, green) that form the stromal network of the follicle. Marginal reticular cells (MRCs, purple) are found between the subcapsular sinus (SCS) and follicle and involved in antigen transport between the SCS and the FDCs in the follicle. T and B cells reside in the LN for 12–18 h, after which they egress at cortical sinuses into efferent lymphatic vessels for recirculation through the blood. Lymphatic vessels are lined by lymphatic endothelial cells (LECs, red) and express signals that promote lymphocyte egress for recirculation, and chemokines such as CCL21, which promotes the transmigration of antigen-bearing DCs as they traffic from peripheral sites in the lymph.

CXCL13 to attract B cells, which initially enter LNs via CCR7-mediated mechanisms. FDCs also express B cell activating factor (BAFF), which helps recruit and activate B cells in the follicle (Allen and Cyster, 2008). It has recently been shown that FRCs in or near the B cell follicle are also a significant source of BAFF (Cremasco *et al.*, 2014). Naïve lymphocytes are retained in the LN through a combination of CCR7-mediated retention and sphingosine-1 phosphate receptor-1 (S1PR1)-mediated egress signals; lymphocytes transiently downregulate S1PR1 in the blood and regain expression of this receptor within tissues (Matloubian *et al.*, 2004). Reexpression of

S1PR1 is required for lymphocyte egress, which occurs at cortical sinuses where the LECs lining this structure produce and export sphingosine-1 phosphate (S1P), the ligand for S1PR1 (Grigorova *et al.*, 2009). The major source of S1P in blood is red blood cells, whereas tissue stromal and myeloid cells express enzymes that degrade S1P, keeping the S1P concentration low in tissues. Therefore, LECs are critical in the egress of lymphocytes from the LN. Peripheral tissue LECs, through their expression of CCL21, also play an important role in controlling T cell and DC migration from the tissues, into lymphatics and the LN. Activated antigen-bearing DCs trafficking from peripheral sites follow a CCL21 gradient toward the LN (Weber *et al.*, 2013). Once DCs reach the LN, they migrate across the lymphatic vessel and use the CCL19/21 gradients supplied by the FRCs in the cortex to find T cells (Bajenoff *et al.*, 2006), and begin an immune reaction. LECs also support the transmigration of CCR7-expressing T cells via the lymph into the LN (Girard *et al.*, 2012).

Initiation and Regulation of Adaptive Immune Responses by Stromal Cells

Stromal cells also play important roles in coordinating the initiation of T cell responses to infection. The FRC network is absolutely essential to maximize the opportunity for T cells to interact with antigen-bearing DCs that have drained from peripheral sites. The maximization of T cell–DC interaction is chiefly due to the production of the chemokines CCL19/21, which bring CCR7-expressing T cells and DCs together to initiate immune responses (Bajenoff *et al.*, 2006). The paucity of LN T cells (*plt* mouse strain is a line with a spontaneous mutation in the CCL19/21 genes, rendering the mice null for CCL19/21 expression in SLOs (although some expression of CCL21-Leu still occurs in the LECs) (Nakano *et al.*, 1997). Immunization or infection of *plt* mice results in delayed but enhanced immune responses, some of which is mislocalized in the splenic red pulp (Mori *et al.*, 2001; Nakano *et al.*, 2009). Further studies have since shown that mice deficient in CCR7 or CCL19 fail to generate adequate immune responses to challenge (Forster *et al.*, 1999; Link *et al.*, 2007), most likely due to the lack of normal LN architecture in the absence of these ligands. A recent study has since shown that acute depletion of FRCs from normal intact adult LNs also results poor initiation of immune responses due to a lack of T cells and DCs in the absence of FRCs, showing that the presence of FRCs, and not just their ability to create the LN structure, is important for the initiation of immune responses (Cremasco *et al.*, 2014; Denton *et al.*, 2014). Interestingly, Ludewig and colleagues have shown that, while a FRC-like network of stromal cells is formed in the absence of FRC-specific lymphotoxin beta receptor (LT β R) signaling, the ‘maturation’ of FRCs through LT β R during development is essential for the initiation of antiviral immune responses (Chai *et al.*, 2013).

It is well known that FRCs actively respond to infection and immunization, proliferating and increasing in number as the LN swells in size (Denton *et al.*, 2014; Yang *et al.*, 2014). Curiously, the FRC expansion is typically delayed relative to that of the CD45⁺ cells, and continues with the ongoing expansion of antigen-specific T cells, suggesting that the early

increase in naïve lymphocytes in the LN during an immune reaction may instruct the expansion of stromal cells (Yang *et al.*, 2014). Stromal cells undergo a number of transcriptional changes in response to inflammation (Malhotra *et al.*, 2012), and a decrease in CCL19/21 and CXCL13 expression has been observed in responding lymph nodes during infection (Mueller *et al.*, 2007), suggesting that stromal cell responses to infection or immunization may help shape the immune response. For example, the expression of retinoic acid by mesenteric LN stromal cells preferentially induces a gut-homing phenotype in activated T cells (Hammerschmidt *et al.*, 2008). Interestingly, recent studies suggested that LN stromal cells, in particular LECs and FRCs, can suppress T cell proliferation *in vitro* (Khan *et al.*, 2011; Lukacs-Kornek *et al.*, 2011; Siegert *et al.*, 2011). This is dependent on nitric oxide synthase (Nos)2 production by the stromal cells, induced by T cell-derived interferon (IFN)- γ . IFN γ -mediated upregulation of Nos2 expression by FRCs has also been described *in vivo*, and this occurs very early in a T cell-mediated response (Lukacs-Kornek *et al.*, 2011), or within 24–28 h of infection (Siegert *et al.*, 2011). While bone marrow chimeric experiments could not directly demonstrate that stromal cell-derived Nos2 could suppress endogenous antiviral T cell responses, another study has since shown that depletion of FRCs once an immune response is established, and during a phase of active T cell proliferation and differentiation, did not significantly alter the ongoing immune response or result in release T cells from any suppressive effect of FRCs (Denton *et al.*, 2014). It is important to note, however, that these depletion experiments were done at a later phase of the immune response than when virally-induced Nos2 upregulation was observed, suggesting that at this stage of the response, FRC-mediated suppression would not occur. This latter study also demonstrated that, while it has been predicted that relinquishment of stromal control over T cell responses may be important for the optimal differentiation of activated T cells (Mueller *et al.*, 2007), depletion of the stromal cells themselves does not alter the resultant immune response. Taken together, studies thus far suggest that once initiated, T cell responses are independent of the FRC network, although the responses of stromal cells early in infection may help guide the development of immune responses.

The stromal cells in the B cell follicle also undergo significant changes during an immune reaction, and these changes promote the formation of germinal centers (GCs), in which develop long-lived high-affinity antibody-secreting B cells. In addition to the expression of CXCL13, FDCs influence B cell biology through the expression of complement (CR) and Fc receptors, BAFF and a range of adhesion molecules (reviewed in (Allen and Cyster, 2008)). During the immune response, the B cell follicle swells and the stromal network undergoes considerable changes, including an increase in FDCs and the conversion of T cell zone-resident stromal cells into CXCL13-expressing FDC-like cells that delineate the new follicle boundary (Mionnet *et al.*, 2013). As the GC develops, B cells migrate toward the T-B border where they present antigen to and receive costimulatory signals from T helper cells. The B cells that received further stimulation then migrate back into the GC, proliferate, undergo somatic hypermutation and develop into long-lived memory B cells or plasma cells.

The GC reaction requires interactions with a unique subset of CD4 + T cells, termed T follicular helper cells (Tfh), which promote the selection of high-affinity antibody-secreting B cells in the GC (Linterman *et al.*, 2012). Depletion of FDCs prior to immunization reduces B cell motility and prevents GC formation, while the disruption of FDC networks during the GC reaction leads to disruption of B cell clustering and results in B cell death (Wang *et al.*, 2011), suggesting that FDCs are important to both the initiation and continued function of GCs. Moreover, the recruitment of Tfh is dependent on FDC-derived chemokines: as Tfh differentiate from CD4 + T cell in the T cell zone they upregulate CXCR5 and lose expression of CCR7, and become responsive to CXCL13-mediated migration signals from FDCs in the GC (Ansel *et al.*, 1999). The GC separates into two distinct zones, termed the light and dark zone. Movement of B cells between these zones is required for proper B cell differentiation, and the differential expression of CXCL13 and CXCL12 in the light and dark zones, respectively, is thought to control B cell movement between these zones (Allen and Cyster, 2008). FDCs also directly present antigen to B cells, and thus are integral to the selection of high-affinity B cell clones, while their ability to trap antigen in the form of immune complexes, through expression of CRs, allows them to act as a long-term reservoir for antigens. FDCs are thought to acquire antigen from multiple sources, including through the lymph, which drains via the SCS and conduit network to FDCs; direct capture from antigen-bearing DCs and macrophages; and ‘hand-off’ from B cells via CRs (Allen and Cyster, 2008). Bajenoff and colleagues recently demonstrated that while FDC networks expand during GC reactions, the new cells are generated by the differentiation of MRCs into FDCs, rather than proliferation of FDCs themselves (Jarjour *et al.*, 2014). Given that MRCs line the region between the follicle and the SCS, this suggests that MRCs may capture antigen at the SCS and maintain the antigen depot as they differentiate into FDCs in the GC.

Regulation of Peripheral Tolerance by Stromal Cells

Tolerance is an important mechanism for the prevention of autoimmunity, and is chiefly achieved by deletion, or inactivation, of self-reactive T cell clones. Tolerance can occur in two distinct ways: central tolerance, which occurs in the thymus; and peripheral tolerance, which is extrathymic. Lymph node stromal cells have recently been shown to be an important contributor to peripheral tolerance. Central tolerance is chiefly mediated by autoimmune regulator (AIRE)-mediated expression of peripheral tissue antigens (PTAs), which induces deletion of reactive clones during thymic maturation. While a population of AIRE-expressing stromal cells has been identified in SLOs (Gardner *et al.*, 2008), AIRE-independent expression of PTAs in LN stromal cells has also been described. Both FRCs and LECs are adept at presenting model PTAs and inducing tolerance to endogenous antigens, in both inflammatory and steady-state conditions (Cohen *et al.*, 2010; Fletcher *et al.*, 2010), although LECs seem more proficient in this capacity than FRCs. LN stromal cells have recently been shown to acquire peptide/MHC class II complexes from DCs and present these complexes to induce antigen-specific

tolerance of CD4 + T cells (Dubrot *et al.*, 2014). Considering that LN FRCs are specialized mesenchymal stromal cell, it is tempting to speculate that mesenchymal stromal cells in other tissues may exhibit similar tolerizing behavior, in both steady-state and inflammatory conditions, which may contribute to poor T cell-mediated clearance of inflammatory lesions.

Stromal Cell Regulation of Immune Responses in Peripheral Tissues

Stromal Cells in Induced Tertiary Lymphoid Organs

Tertiary lymphoid organs (TLOs) are typically defined as lymphoid-like structures, containing clearly demarcated T and B cell zones that develop after birth. TLOs form during viral and bacterial infections, chronic transplant rejection, autoimmune disorders, cancer, and other detrimental pathologies (reviewed in Neyt *et al.* (2012)). TLOs have structure highly similar to SLOs, including FDC and FRC populations that control the localization of B and T cells through expression of CXCL13 and CCL21, respectively. In response to influenza A virus infection, a TLO forms in the lung, termed inducible bronchus-associated lymphoid tissue (iBALT), and this structure is particularly well-studied. The iBALT generates robust T and GC B cell responses, good enough to clear an infection in the absence of SLOs (Moyron-Quiroz *et al.*, 2004). Moreover, the presence of iBALT prior to infection significantly improves survival, viral clearance and antibody production and decreases lung immunopathology and infection-associated morbidity (Wiley *et al.*, 2009). While iBALT formation is likely important for early antigen-specific immunity to a subsequent infection (Moyron-Quiroz *et al.*, 2006), the maintenance of immune reactions by local TLOs can also be detrimental to the host. In a number of autoimmune diseases TLOs increase with disease pathogenesis; are associated with more severe immunopathology; and promote disease-associated mortality in mouse models (Astorri *et al.*, 2010; Lochner *et al.*, 2011), presumably through promoting the production of auto-reactive T and B cells. While antigen-specific responses are detected in TLOs, it is not known whether TLOs directly induce autoimmunity or merely promote the established disease.

Initiation of Tissue Inflammation

Whilst discussion to this point has been limited to stromal cells within lymphoid organs, BECs and fibroblasts in peripheral tissues also have important roles in modulating the immune system. Upon initiation of an inflammatory response cytokines such as tumor necrosis factor (TNF α) and IL-1 act on BECs inducing the expression of vasodilatory agents such as Nos, the upregulation of adhesion molecules including P-selectin, vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) and chemokines (Mai *et al.*, 2013). The BEC response to infection does not consist of a binary switch between resting and activated; adhesion molecule and chemokine expression are modulated by the surrounding milieu, for example, expression of CXCL10 and E-selectin is increased in T helper type 1 (Th1) biased environments (Austrup *et al.*, 1997). Whilst these may be seen

to be responses to the surrounding cytokine environment rather than direct organization of the immune response by BECs, BECs can directly sense pathogen associated molecular patterns (PAMPs) through pattern recognition receptors (PRRs) and can direct appropriate immune responses. Toll-like receptor (TLR)4 expression by endothelium has been shown to be important for the recruitment of neutrophils to sites of gram-negative bacterial infections (Andonegui *et al.*, 2003). BECs have also been shown to express major histocompatibility complex (MHC) I and II (von Willebrand *et al.*, 1985) and costimulatory molecules (Khayyamian *et al.*, 2002) leading to the suggestion that BECs may interact with memory cells and may recruit antigen-specific memory CD4 + T cells during recall responses in peripheral tissues (Manes and Pober, 2008). More recently it has been shown that once CD4 + T effector cells have been recruited to a site, BECs upregulate MHCII in response to IFN γ and this allows recruitment of antigen-specific regulatory T (Treg) cells which can then lead to resolution of the inflammatory response (Fu *et al.*, 2014). Under steady state conditions, however, endothelial cells should not be seen as quiescent. In the liver BECs capture and cross present self antigens and recruit CD8 + T cells and induce tolerance in a manner analogous to that seen by LECs in the LN (von Oppen *et al.*, 2009; Cohen *et al.*, 2010). It is, however, difficult to ascribe a role to resting state BECs due to the great degree of diversity in BEC phenotype throughout an organism both in surface markers and in function (Abbott *et al.*, 2006; Kumar *et al.*, 1987). As such, it is possible that BECs in different organs have entirely different roles in regulating the immune response at steady state which are yet to be uncovered.

Whilst BECs regulate the interface between the blood and the parenchyma and thus have an obvious role in regulating the immune response, fibroblasts found within the tissue also have important roles to play. At the most basic level fibroblasts are responsible for deposition of the extracellular matrix (ECM) along which immune cells travel within tissues once they extravasate (Kalluri and Zeisberg, 2006). ECM is not, however, a passive scaffold and modifications in the tensile strength and composition of ECM have dramatic impacts on cellular behavior (Levental *et al.*, 2009). However, a review of the effect of ECM on immune responses is beyond the scope of this article and has been reviewed relatively recently (Sorokin, 2010). Fibroblasts, like BECs, also express PRRs and have roles in initiating immune responses. Synovial fibroblasts have been shown to respond to both Tenascin-C and lipopolysaccharide (LPS) in a TLR4-dependent manner to produce distinct combinations of IL-6, IL-8 and TNF α (Midwood *et al.*, 2009). While fibroblasts can exhibit remarkably distinct transcriptomic profiles (Chang *et al.*, 2002), fibroblasts identified by expression of fibroblast activation protein-alpha (FAP) have very similar gene expression profiles (Roberts *et al.*, 2013). Indeed, this transcriptome is remarkably pro-inflammatory, and has much in common with that of cancer-associated fibroblasts (CAFs), which also express FAP (Erez *et al.*, 2010; Feig *et al.*, 2013; Roberts *et al.*, 2013). The fact that FAP + fibroblasts are primed for expression of inflammatory mediators, coupled to their apparent lack of TLR expression, suggests that the coordinated response to multiple stromal cell types is important for the initiation of inflammation, and this

inflammatory process is essential for the wound healing response in multiple tissues (Eming *et al.*, 2007).

While stromal cells are important for the initiation of inflammation, they also play a role later in the response. Once an inflammatory infiltrate has been established fibroblasts can produce survival factors such as type I IFN, IL-15, and BAFF due to TLR engagement which prolong the survival of the inflammatory lesion (Benito-Miguel *et al.*, 2012). Indeed, the removal of these survival factors for inflammatory cells has been suggested as a mechanism by which fibroblasts promote the resolution of inflammation (Buckley *et al.*, 2001). Fibroblasts have been posited to have a more active role in resolving inflammation through active suppression of immune responses at sites of inflammation. Mesenchymal stem cells (MSCs), a type of stromal cell, have been defined by their ability to differentiate into adipocytes, chondrocytes, and osteoblasts. They have been isolated based on a variety of different surface markers which vary by strain of mouse (Peister *et al.*, 2004). Most work demonstrating an active role for MSCs has been carried out *in vitro* with ex vivo-expanded MSCs, which once activated by monocyte derived cytokines, suppress T cell proliferation (Groh *et al.*, 2005). Indeed this further work suggested that these effects could differentially affect antigen-specific T cells (Karlsson *et al.*, 2008). It has also been shown *in vitro* that these cells can alter macrophage activation through production of soluble mediators (Maggini *et al.*, 2010). These roles, if representative of what occurs *in vivo*, could indicate important functions for fibroblasts in actively switching the phenotype of an inflammatory lesion to that of an immune suppressive environment suitable for regenerative wound healing rather than through repair. Studies of MSC function *in vivo*, however, do not address the normal role for MSCs as they rely on transfer of high numbers of ex vivo-expanded MSCs (Yanez *et al.*, 2006). As such it is unclear whether these functions are important in normal wound healing responses. As with BECs, however, it is important to recognize the incredible heterogeneity found amongst fibroblasts (Aubin, 2001) whilst ascribing specific roles to them. Indeed within the skin fibroblasts from different sites showed as much transcriptional variation as seen between leukocyte populations (Chang *et al.*, 2002). However, fibroblasts isolated from distinct sites based on expression of FAP had similar transcriptomic profiles suggesting that populations common to diverse sites may be parsed out through the use of diverse surface markers (Roberts *et al.*, 2013). As such diverse populations of fibroblasts may have distinct, even opposing, roles within tissues during the initiation and resolution of inflammation.

Inflammatory Diseases

During chronic inflammatory conditions the roles played by BECs and fibroblasts can become maladaptive. As with macrophage polarization, BECs and fibroblasts can ‘polarize’ in different ways, which may contribute to pathology by various means. For example, stromal cells can both prevent an effective immune response or support an excessive response. Cancer provides a model where both BECs and fibroblasts have been shown to have immunosuppressive roles that promote tumor growth (Buckanovich *et al.*, 2008; Kraman *et al.*, 2010).

Whilst many tumors are immunogenic and therapeutic vaccines have been shown to induce adequate T cell responses, clinical efficacy of these responses has been limited (DuPage *et al.*, 2011). Endothelial cells microdissected from human ovarian tumors lacking T cell infiltration were shown to have upregulated Endothelin B receptor and blockade of this receptor led to increased tumor infiltration and increased efficacy of vaccination (Buckanovich *et al.*, 2008). Fibroblasts also have been shown to have effects on the ability of lymphocytes to infiltrate tumors. Fibroblasts activated in the tumor microenvironment express matrix components, proteases and other ECM modifying enzymes altering the mechanical properties of the tissue (Kalluri and Zeisberg, 2006; Levental *et al.*, 2009). Using real time imaging of slices of human lung tumors Salmon *et al.* showed that dense collagen fibers aligned around tumor nests excluded T cells from the cancer cells and that disrupting these structures allowed lymphocytes to infiltrate these structures (Salmon *et al.*, 2012). Recent studies have also identified CXCL12 as having a role in the exclusion of CD8 + T cells from tumors and this could be overcome by administering AMD3100, a CXCR4 antagonist (Feig *et al.*, 2013). Fibroblasts in LLC tumors and autochthonous pancreatic tumors were found to be the major source of CXCL12 indicating that fibroblasts can, similarly to BECs, assume a phenotype excluding T cells from the tumor (Feig *et al.*, 2013). Interestingly, despite this apparent role in immune cell exclusion when CAFs, isolated by their expression of platelet-derived growth factor receptor- α (PDGFR α), were isolated from skin carcinomas, pancreatic and mammary tumors and their transcriptome analyzed by microarray whilst they were found to be relatively heterogeneous, a pro-inflammatory gene signature did emerge (Erez *et al.*, 2010). This indicates that CAFs drive tumor promoting inflammation whilst excluding the potentially tumoricidal tumor-reactive lymphocytes. In fact CAFs have been shown to express monocyte chemotactic protein 1 (MCP-1) and that not only recruits monocytes but also biases their differentiation toward the pro-tumor M2 tumor-associated macrophage (TAM) phenotype (Comito *et al.*, 2014). The pro-inflammatory gene signature observed by Erez *et al.* could be induced in dermal fibroblasts by coculturing them with conditioned media from carcinoma cells indicating a close cross regulation between carcinoma cells, CAFs and TAMs (Erez *et al.*, 2010). Although this signature was present, it varied between PDGFR α + cells from different sources, and these may not represent the total pool of fibroblasts. Indeed the heterogeneity in tumor fibroblast populations may not simply be due to the heterogeneity observed in tissue resident fibroblasts previously alluded to (Chang *et al.*, 2002), but may also be due to heterogeneous origins of different CAF populations. Kidd *et al.* recently looked at different mesenchymal subsets within the tumor microenvironment and characterized their origins. They found that some cells marked by fibroblast specific protein 1 (FSP-1) originated from the bone marrow whilst others such as pericytes appeared to originate from adjacent tissue (Kidd *et al.*, 2012). As such it is again important to bear in mind that the markers used in individual studies will affect the populations of fibroblasts being examined.

BECs and fibroblasts also have important roles in driving pathological immune responses such as in rheumatoid

arthritis (RA). BECs are persistently activated in the inflammatory milieu of the RA synovium and express high levels of adhesion molecules and chemokines (Koch *et al.*, 1991). However, the changes seen in BECs in RA appear to be similar to those occurring in inflammatory conditions, however, these become persistent and maladaptive when the inflammatory environment persists and BECs continue to recruit further inflammatory cells. Fibroblasts within the synovium can also become activated in similar ways to those mentioned earlier, by TLR stimulation or in response to leukocyte-derived signals such as cytokines or microparticles, and they may then express a multitude of pro-inflammatory cytokines and chemokines, including IL-6, type I IFN, BAFF, which promote the inflammatory process (Benito-Miguel *et al.*, 2012). However, in RA and other chronic inflammatory diseases fibroblasts do not stop producing these factors and as such the damaging inflammatory process continues (Buckley *et al.*, 2004). Indeed implantation of diseased cartilage in severe combined immunodeficiency (SCID) mice showed that these activated fibroblasts could travel through the vasculature and spread to unaffected healthy cartilage implanted at a distal site potentially explaining the tendency of RA to spread from affected to previously unaffected joints indicating a critical orchestrating role for stromal cells in this system (Lefevre *et al.*, 2009). Indeed in many chronic inflammatory conditions such as rheumatoid arthritis, colitis, systemic fibrosis, and kidney fibrosis it appears that there is epigenetic modulation of the fibroblast cells giving them a more stable pro-inflammatory phenotype (Bechtel *et al.*, 2010). This may allow cells which do migrate to spread the inflammatory state even in the absence of new TLR stimulation or lymphocyte-derived signals. Whether the activation of the stromal cells drives or merely contributes to the disease progression is, again, unknown although fibroblasts remain an attractive therapeutic target due to their pro-inflammatory profile.

Targeting Stroma

With so many roles in inflammation it is tempting to view stromal cells as attractive therapeutic targets. As stated, infusion of ex vivo-expanded fibroblast populations, either FRCs or MSCs, have been shown to have positive effects in many inflammatory conditions (Fletcher *et al.*, 2014; Yanez *et al.*, 2006). Strategies able to modulate the pro-immune functions of fibroblasts at sites of chronic inflammation would potentially allow resolution of autoimmune lesions whilst skewing CAFs away from their immune suppressive phenotype could have benefits in cancer therapy, and indeed could complement current checkpoint blockade therapies (Feig *et al.*, 2013). In order to capitalize on these promising therapeutic directions, however, more work is needed to understand the heterogeneity of the populations being studied. Furthermore, if we are to avoid off-target effects it is important to understand the roles played by stromal cells in other tissues, which could be affected by therapeutic interventions and their relationships to the pathologic stromal cells being targeted. Previous work suggested that fibroblasts expressing FAP were restricted to sites of wound healing and cancer, however, ablation of these cells experimentally led to cachexia and anemia (Roberts *et al.*, 2013; Tran *et al.*, 2013). It is possible that even with better

understanding of markers of stromal populations such blunt approaches, targeting a single marker, will be too nonspecific to provide direct benefit. Future work identifying pathways important for the immune modulatory roles of fibroblasts is also important and has shown promising results in cancer therapy (Feig *et al.*, 2013).

Introduction

Chemokines, the largest family of cytokines, are named for their chemoattractant activities. Defined by structure not function, chemokines have a highly conserved tertiary structure due to their conservatively spaced disulfide-bonded cysteines. Chemokines are classified by numbers and location of cysteine in their amino acid sequence, with subfamilies distinguished by CXC, CC, XC, and CX3C motifs followed by the letter 'L' and a number. They can be further classified by additional motifs such as the Glu-Leu-Arg (ELR) N-terminal motif of the CXC subfamily or the position of the sixth cysteine found either in the C-terminal domain or between C-2 and C-3 of the CC subfamily (all of which have 6 cysteines). Chemokines can exist as monomers, dimers, tetramers, and even complex quaternary structures which occur when they bind to glycosaminoglycans (GAGs), carbohydrates containing amino sugars, on the cell surface. Tethering to the extracellular matrix (ECM) or GAGs on the cell surface (except in the case of CX3CL1/fractalkine and CXCL16 which have transmembrane domains), chemokines bind to chemokine receptors. Chemokine receptors are members of the seven-transmembrane domain superfamily of G protein-coupled receptors; their function stems from a single polypeptide chain which is responsible for chemokine binding, membrane anchoring, and carrying signaling domains. Chemokine receptor nomenclature is mostly determined by the ligand subfamily (e.g., CXC or CC) followed by R and a number (Bacon *et al.*, 2002; Baggiolini *et al.*, 1997; Murphy, 1996).

Chemokines coordinate hematopoietic cell trafficking covering the range of mature leukocytes and hematopoietic stem cell (HSC) and progenitor cell (HPC) populations. The function of chemokines within these cell populations allows for further classification into two more defined chemokine systems: the homeostatic and inflammatory systems (Le *et al.*, 2004). The homeostatic system of chemokines regulates hematopoiesis, the process by which HSCs self-renew and differentiate to form the peripheral blood lineages, and coordinate immune surveillance, accomplished through constitutively expressed chemokine ligands and receptors within specific tissues. Examples of homeostatic chemokine receptors include: CXCR4 (a receptor for CXCL12) on hematopoietic stem and progenitor cells, CXCR5 on naïve B cells, CCR7 on mature dendritic cells and naïve T cells, and gut and skin-specific T cell homing receptors CCR9 and CCR10, respectively. The inflammatory system is characterized by the ability of 'danger signals' (produced, for example, following tissue damage or infection) to regulate chemokine and chemokine receptor expression where chemokines are inducible and chemokine receptors can be either inducible (in adaptive immunity) or constitutively expressed (in innate immunity).

Here we examine roles chemokines play within the bone marrow (BM) microenvironment focusing primarily on the

role of the homeostatic chemokine CXCL12 and one of its receptors, CXCR4, on regulating HSC/HPC homing to and maintenance within their preferred niches in the BM. We also examine roles of CXCL12 in controlling neutrophil and B cell production within BM.

Role of CXCL12 in Homing to BM

HSCs and HPCs circulate through the bloodstream and extravasate into the BM. The ability of HSCs to home to the BM was first demonstrated in mice whose spleen was shielded from a dose of lethal total body irradiation. These mice still exhibited hematopoietic recovery suggesting that repopulating cells residing within the spleen could home to the BM (Jacobson *et al.*, 1949; Lorenz *et al.*, 1951); but how did these cells know where to go? Like most of their mature counterparts, homing of HSCs and HPCs to a specific tissue site requires the process of cell tethering/rolling along the vascular endothelial as controlled by the interaction of selectins and carbohydrate ligands, the activation of the cell by chemokine binding to G protein-coupled receptors to mediate firm adhesion to the vascular wall by interactions of integrins with adhesion molecules of the Ig superfamily, and by the extravasation of the cell through the basal lamina ECM mediated via chemokine signaling (Muller, 2014).

As HSCs and HPCs circulate through the blood, they encounter and interact with BM vascular endothelial cells of BM venous sinuses. The sinus wall is composed of endothelial cells, basement membrane and a layer of adventitial cells (Inoue and Osmond, 2001). Within the endothelial cell layer are multiple sites in which abluminal and luminal membranes are fused, forming diaphragmed fenestrae (Burdon *et al.*, 2008; Levesque *et al.*, 2002). It is at this site that HSCs and HPCs are believed to migrate through the blood-BM barrier. BM sinusoidal endothelial cells constitutively express vascular cell adhesion molecule-1 (VCAM-1), E- and P-selectins (Frenette *et al.*, 1996, 1998; Mazo *et al.*, 1998; Miyake *et al.*, 1991; Papayannopoulou *et al.*, 1995). When HSCs and HPCs expressing P-selectin glycoprotein ligand-1 (PSGL-1) and high levels of very late antigen-4 (VLA-4/integrin $\alpha 4 \beta 1$) interact with VCAM-1, E- and P-selectin, they are able to roll along the vascular endothelial layer until they encounter the proper chemokine signal. CXCL12 is responsible for activation of HSCs and HPCs allowing for firm, shear-resistant adhesion to BM endothelium, although stem cell factor (SCF) and FMS-like tyrosine kinase-3 (FLT-3) can synergize enhancing migration. Interaction of BM endothelial CXCL12 with CXCR4 on HSC or HPC surfaces mediate activation of VLA-4, VLA-5 (integrin $\alpha 5 \beta 1$) and lymphocyte function-associated antigen-1 (LFA-1/integrin $\alpha L \beta 2$) via the PI-PLC and PI3-K pathways. This leads to ERK and Pyk2 activation, allowing for firm adhesion to take place (Bonig *et al.*, 2008; Petit *et al.*, 2005).

Integrins exist on the surface of HSC/HPC in a low-affinity, 'bent' conformation which upon activation by CXCL12: CXCR4 signaling alters integrin conformation allowing for integrin binding to its ligand so that the cell can extravasate and migrate into the BM. Adhesion molecules believed to be involved in the extravasation process include platelet-endothelial cell adhesion molecule-1 (PCAM-1/CD31), CD99, CD31, VLA-4, VLA-5, and VLA-6 (Imbert *et al.*, 2006; Yong *et al.*, 1998).

There is substantial evidence for the importance of CXCL12: CXCR4 interaction in HSC and HPC migration. For example, CXCR4^{-/-} and CXCL12^{-/-} mice demonstrate profound defects in the ability of fetal liver HSCs and HPCs to migrate/populate BM suggesting that CXCL12: CXCR4 signaling is important in marrow colonization and, therefore, in homing of these cells to the proper BM microenvironment during development (Ma *et al.*, 1998; Nagasawa *et al.*, 1996; Zou *et al.*, 1998). In adult models, CXCL12: CXCR4 plays a major role in homing to and mobilization from BM of HSCs and HPCs. Blocking CXCR4 function with neutralizing anti-CXCR4 antibodies prevents hematopoietic recovery following transplantation of human CD34⁺ cells in non-obese diabetic/severe combined immunodeficient (NOD/SCID) mice (Peled *et al.*, 1999). Overexpression of CXCR4 on human CD34⁺ cells enhanced the migration of these cells into NOD/SCID mice thus enhancing hematopoietic recovery following transplantation (Broxmeyer *et al.*, 2003; Kahn *et al.*, 2004).

Since HSC and HPC homing to BM following transplantation is a critical step in engraftment, CXCL12 signaling modulators have been utilized. One CXCL12 modulator is the enzyme CD26/dipeptidylpeptidase IV (DPP4). CD26 is expressed on surfaces of multiple cell types, and functions as a cell surface serine protease that selectively cleaves the N-terminal penultimate proline or alanine amino acids of various growth factors and cytokines including CXCL12 (Broxmeyer, 2008; O'Leary *et al.*, 2013; Ou *et al.*, 2013). Inhibition of DPP4 with diprotin A (Ile-Pro-Ile peptide) enhances chemotaxis of both human and mouse HSCs/HPCs *in vitro* (Christopherson *et al.*, 2002). *In vivo* pretreatment of recipient mice with diprotin A enhances engraftment of donor HSCs and HPCs following transplantation further supporting the role of CD26 as a modulator of CXCL12-mediated migration/homing to BM (Christopherson *et al.*, 2004). Another method to enhance migration of HSCs and HPCs towards a CXCL12 gradient is by priming the cells to respond more robustly to lower concentrations of CXCL12 (Levesque *et al.*, 2010; Moll and Ransohoff, 2010). Fibrinogen, fibronectin, complement C1q, complement C3a, platelet-derived microvesicles, hyaluronic acid, thrombin, and bioreactive lipids prime HSCs and HPCs to better migrate toward low concentrations of CXCL12. This is thought to occur by recruiting CXCR4 into specialized plasma membrane domains called lipid rafts which allows for the receptor to be in closer proximity to downstream signaling components. The use of these 'primers' is also associated with a highly proteolytic microenvironment due to increased matrix metalloproteinase (MMP)-2 and MMP-9 expression. These results, amongst others, strongly suggest that CXCL12: CXCR4 signaling is required for optimal migration of HSCs and HPCs into BM; however, once in the BM CXCL12 also plays a role.

Role of CXCL12 in HSC and HPC Maintenance within BM Niches

Within the BM microenvironment exist regions enriched with CXCL12 where HSCs home to, are retained in, and which help to maintain their self-renewal and differentiation potential through inhibiting G₀→G₁ cell cycle progression and by increasing the survival of HSCs and HPCs (Broxmeyer, 2001, 2008; Broxmeyer *et al.*, 2003; Mendelson and Frenette, 2014). HSCs and HPCs that home to the BM microenvironment through endothelial sinusoids from blood must navigate the ECM and lodge in marrow parenchyma. Cellular and extracellular signals provided within CXCL12-enriched regions define the potential regulatory function of that particular niche. The two primary HSC niches are the perivascular niche and the osteoblastic or endosteal niche which is located at the bone surface (Mendelson and Frenette, 2014). There is some disagreement as to the role of each niche in the maintenance of HSCs and HPCs with some believing that the endosteal region of the BM is more important in maintaining quiescent HSCs, while others suggest that the perivascular region of the BM plays a larger role in HSC maintenance (Levesque *et al.*, 2010; Mendelson and Frenette, 2014; Moll and Ransohoff, 2010).

Recent studies have attempted to define the cells responsible in maintaining HSC and HPC numbers and function within BM, thus hinting at the importance of each particular niche. It is clear that CXCL12 is essential in maintaining and retaining HSCs and HPCs within the BM. Key cell types were found to play an important role in producing or regulating CXCL12 in the BM. This includes perivascular mesenchymal stem and progenitor cells (MSPCs), perivascular stromal cells (e.g., CXCL12-abundant reticular or CAR cells), endothelial cells, hematopoietic cells (e.g., macrophages), and sympathetic neurons (Ding and Morrison, 2013; Greenbaum *et al.*, 2013; Mendelson and Frenette, 2014). Perivascular MSPCs/stromal cells express the highest concentrations of CXCL12 followed by osteoprogenitors, endothelial cells, osteoblasts, and finally hematopoietic cells. Animal models in which specific HSC/HPC niche cells have conditionally deleted *Cxcl12* were utilized to determine the role of these different CXCL12-producing niche components on HSC and HPC maintenance and retention.

To examine perivascular MSPCs and stromal cells, the genetic models *Prx1-cre*, *Nestin-Gfp*, and *Lepr-cre* were utilized. *Cxcl12* deletion in nestin-negative mesenchymal progenitors using *Prx1-cre* mice demonstrated a significant loss of HSC and HPC numbers in BM associated with increased HSC number in spleen, decreased long-term repopulating activity and loss of HSC quiescence (Ding and Morrison, 2013; Greenbaum *et al.*, 2013). Deletion of *Cxcl12* in *Lepr-cre* cells significantly induced mobilization of HSCs and HPCs to peripheral blood and spleen, but had no effect on HSC maintenance, suggesting that these cells play a role in HSC/HPC retention within the BM (Ding and Morrison, 2013; Ding *et al.*, 2012). Thus, CXCL12 production by MSPCs plays an important role in HSC and HPC retention, maintenance and self-renewal. Examining the role of CXCL12 production in endothelial cells by deleting *Cxcl12* in Tie2⁺ cells, demonstrated modest decreases in HSC numbers and repopulating capacity without changes to HPC numbers, suggesting that the CXCL12 produced by endothelial

cells may play a role in HSC maintenance but has little effect on HPCs. Upon examining the role of CXCL12 production by osteoprogenitors (Osterix-*cre* mouse model) and osteoblasts (Col2.3-*cre* mouse model) by deleting *Cxcl12*, it was discovered that CXCL12 from osteoprogenitors and osteoblast had no role on HSC maintenance (Ding and Morrison, 2013). However, both cell types assist in maintaining HPC numbers and helped with HPC retention within the BM, suggesting that CXCL12 production by MSPCs, and to lesser extent endothelial cells, plays an important role in maintaining HSCs and that the osteoblastic lineage cells play a larger role in HPC maintenance.

Another method of regulating CXCL12 expression within the BM microenvironment is through the sympathetic nervous system. Sympathetic nerves are in close contact with nestin-expressing MSPCs. Sympathetic nerves create an adrenergic signal (which responds to circadian rhythms) that down-regulates CXCL12, Kit Ligand, and VCAM-1 gene expression, leading to HSC/HPC mobilization (Katayama *et al.*, 2006; Mendez-Ferrer *et al.*, 2010). Interestingly, macrophages within the BM microenvironment seem to have an antagonistic effect compared to adrenergic signals. Like the sympathetic neurons, macrophages are also in close contact with the nestin-expressing MSPCs and through receiving an unknown signal can induce CXCL12 expression (Chow *et al.*, 2011; Christopher *et al.*, 2011). Thus, both sympathetic nerves and macrophages regulate HSC/HPC retention within the BM.

CXCL12 in HSC and HPC Mobilization

Utilizing the knowledge that CXCL12 is an important homing signaling for HSC and HPC to migrate towards adult BM, studies were performed that either increased CXCL12 levels in the periphery or decreased the ability for CXCL12 to bind or signal through CXCR4. When CXCL12 levels in the peripheral circulation were upregulated through intravenous injection of an adenoviral vector expressing CXCL12 into SCID mice, there were significant increases in numbers of HPC (i.e., colony-forming units-granulocyte-macrophage) and increases in cells with stem cell potential (i.e., colony-forming units-spleen and long-term reconstituting HSCs) mobilized into the periphery (Hattori *et al.*, 2001). Mobilized human CD34⁺ cells also demonstrated a decrease in CXCR4 expression suggesting an important role in CXCL12: CXCR4 for regulating the mobilization of HSCs and HPCs (Dar *et al.*, 2006; Vagima *et al.*, 2011).

A major method of stimulating HSC/HPC mobilization is through the use of intravenous granulocyte colony-stimulating factor (G-CSF), the most widely used mobilization agent in the clinic. G-CSF expression can interrupt CXCL12 retention signals of these cells to remain within their niches. One possible mechanism in which this occurs is through the mediation of proteolytic inactivation of both CXCL12 and CXCR4 (Alvarez *et al.*, 2013; Broxmeyer, 2008; Mendelson and Frenette, 2014). Following activation by G-CSF, neutrophils release elastase and lactoferrin, allowing for further degranulation of neutrophils within the BM stroma. This increase in granulocytic proteases (including elastase and cathepsin) may be responsible for cleavage of important retention mediators such as

VCAM-1, CXCL12, CXCR4, and c-KIT receptor. In addition, increased concentrations of G-CSF was associated with increased expression of CD26 peptidase in CD34⁺CD38[−] human cord blood cell population which correlated with decreased ability of these cells to home towards CXCL12 (Christopherson *et al.*, 2002, 2006). Further supporting these findings, CD26^{−/−} mice demonstrated diminished responses to G-CSF-induced HSC/HPC mobilization, suggesting that CXCL12 cleavage by CD26/DPP4 may be a key mechanistic step (Christopherson *et al.*, 2003). G-CSF also enhances mobilization by inducing expression of plasminogen, a glycoprotein present in the blood plasma and other extracellular fluids that plays a role in dissolution of blood clots following thrombosis (Alvarez *et al.*, 2013; Broxmeyer, 2008; Mendelson and Frenette, 2014). Plasminogen is able to bind BM ECM, be converted into active protease plasmin, and then degrade the ECM. It can also activate other proteases including those within the MMP family including MMP-3,-9,-12, and -13 which can further degrade the ECM and collagen. Therefore, G-CSF plays a critical role in regulating proteases not only by inhibiting the ability of CXCL12 to signal through its receptor but also by enhancing the ability of HSCs/HPCs to migrate by enhancing degradation of collagen and the ECM.

G-CSF also functions to augment CXCL12 expression via indirect means. G-CSF under steady-state conditions and following therapeutic treatment is associated with decreased expression of CXCL12 mRNA in osteoblasts (Semerád *et al.*, 2005). However, it is unclear how this regulation occurs since the osteoblast does not express G-CSF receptors. *In vivo*, therapeutic treatment with G-CSF is associated with increased osteoblast apoptosis due to inhibition of osteoblast differentiation which may contribute to decreased CXCL12 secretion; however, whether this occurs under physiological conditions remains to be seen (Christopher and Link, 2008). *In vivo* studies suggest that macrophages and sympathetic neurons may play a role in G-CSF-mediated increases in osteoblast apoptosis. Following G-CSF exposure, there is an increase not just in osteoblast apoptosis but a decrease in macrophage numbers. This was associated with activation of sympathetic neurons to release norepinephrine in the BM microenvironment (Christopher *et al.*, 2011; Katayama *et al.*, 2006; Lucas *et al.*, 2012; Winkler *et al.*, 2010). Macrophages and sympathetic neurons express G-CSF receptors and by blocking either G-CSF receptor signaling or norepinephrine signaling HSC/HPC mobilization is inhibited, suggesting that macrophages and sympathetic neurons may be regulating osteoblasts. G-CSF signaling also leads to increased CXCL12 expression by BM endothelial cells and megakaryocytes (Eash *et al.*, 2010; Kohler *et al.*, 2011). Thus, this is another way in which G-CSF may regulate HSC and HPC numbers in the periphery.

HSC/HPC mobilization can also be stimulated through the use of CXCR4 antagonists and agonists. AMD3100, a small organic molecule consisting of two cyclam rings connected by 1,4-phenylenebis(methylene) linker, is an antagonist of CXCL12/CXCR4 signaling by binding to CXCR4 (Debnath *et al.*, 2013; Fricker, 2013). Blocking of CXCL12 ability to signal through CXCR4 results in an increased mobilization of HSCs and HPCs to the blood (Broxmeyer, 2008; Broxmeyer *et al.*, 2005). AMD3100 works synergistically with G-CSF to

mobilize HSCs and HPCs. HSCs and HPCs mobilized using both AMD3100 and G-CSF demonstrated increased expression of genes associated with better engraftment following transplantation when compared to cells mobilized with G-CSF alone. CTCE-0021, a CXCR4 agonist peptide, also enhances HSC/HPC mobilization; an effect believed to be mediated by the downregulation of CXCR4 expression on the cell surface (Pelus *et al.*, 2005).

Role of CXCL12 in Maintenance of Neutrophils in BM

CXCL12-depleted adult mice as well as CXCL12^{-/-} embryonic mice demonstrate that CXCL12 is essential in maintaining hematopoiesis (Ma *et al.*, 1998; Nagasawa *et al.*, 1996; Zou *et al.*, 1998). In both models, numbers of HPCs was severely reduced in BM. Furthermore, HPCs from mice that transgenically overexpress CXCL12 displayed enhanced hematopoiesis in both BM and spleen (Broxmeyer *et al.*, 2003). This was associated with increased HPC cycling. *In vitro* studies of HPCs from CXCL12 transgenic mice demonstrated enhanced survival, which was dependent upon CXCL12 signaling through its receptor CXCR4 since utilizing neutralizing antibodies against CXCR4 and AMD3100 blocked these effect of CXCL12 (Broxmeyer *et al.*, 2003). In addition, the use of pertussis toxin, which inhibits G α i protein-linked receptor signaling, also blocked effects of CXCL12 on HPC survival, offering further evidence for the importance of CXCL12 signaling on HPC maintenance (Broxmeyer *et al.*, 2003).

Although CXCL12 is important in maintaining hematopoiesis, the exact BM niche component that regulates this process is unclear. Decreasing numbers of macrophages and osteoblasts in BM decreased numbers of HPC suggesting that the endosteal region of BM is important in maintaining hematopoiesis. A relationship between the osteoblastic niche and hematopoiesis is supported by histological studies demonstrating that HPCs are in close proximity to endosteum (Ueda *et al.*, 2005, 2004). Furthermore, stimulation of osteoclasts with the cytokine RANKL reduced expression of important HPC survival and growth factors such as CXCL12, SCF, and osteopontin along the endosteum resulted in fewer HPCs in BM (Kollet *et al.*, 2006). However, these findings do not correlate with recent work demonstrating no changes in HPC maintenance or numbers when *Cxcl12* was deleted in osteoprogenitors or osteoblasts (Ding and Morrison, 2013; Greenbaum *et al.*, 2013). Further work needs to be performed to understand the roles niche cells play in regulating hematopoiesis.

CXCL12 is important not only in regulation of hematopoiesis, but in maintenance of neutrophil stores as well. Under homeostatic conditions, only 1–2% of total neutrophils at any given time are in the peripheral blood; the rest are stored in the BM (Broxmeyer *et al.*, 1974; Semerad *et al.*, 2002). During emergency situations (such as infection or tissue injury), neutrophil stores in the BM act as a large reservoir of neutrophils that can be released when needed. Like HSC and HPC, neutrophils utilize the venous sinuses as the primary migration site to and from BM. Neutrophils exit from BM and their entrance to the bloodstream is controlled by chemokine signaling from the local and systemic cytokine milieu, binding

and release from various adhesion molecules, and through regulation of protease activity.

Three members of the CXC family of chemokines are thought to control neutrophil egress from the BM: CXCL1 (KC), CXCL2 (MIP-2), and CXCL12. CXCL1 and CXCL2 are members of the ELR-subfamily of CXC chemokines and are expressed by osteoblasts in BM, megakaryocytes, macrophages, neutrophils, and endothelial cells. CXCL1 and CXCL2 bind to CXCR2 on the neutrophil surface causing rapid release of neutrophils into the circulation (Burdon *et al.*, 2005, 2008; Wengner *et al.*, 2008). This occurs under steady-state conditions to replenish neutrophil numbers and under stress conditions such as infection or tissue damage to increase numbers of circulating neutrophils. Neutrophil egress from BM under steady-state conditions is mediated by the VLA-4 on the neutrophil surface and by signaling through CXCR2. VLA-4 integrin engages VCAM-1 on the endothelial surface, stabilizing neutrophil adhesion, inducing neutrophil shape change, and supporting transmigration across the endothelial cell monolayer (Burdon *et al.*, 2005, 2008). Mice that have CXCR2-deficient neutrophils selectively retain neutrophils in the BM and exhibit neutropenia in the circulation, suggesting that signaling through CXCR2 plays a role in neutrophil egress from BM to peripheral blood (Eash *et al.*, 2010).

While in BM, neutrophils express low, but detectable, levels of surface CXCR4. When CXCL12 binds CXCR4 on the neutrophil cell surface, CXCR4 is internalized through a process of receptor recycling; therefore, cells have a large intracellular store of CXCR4 so that a constant concentration can remain on the cell surface during the time in which neutrophils remain in the BM (Martin *et al.*, 2003). CXCR4-deficiency, when specific to the myeloid lineage, causes neutrophilia in mice, as did conditional deletion of CXCL12 (Eash *et al.*, 2009). Thus, CXCL12:CXCR4 signaling is thought to be the key retention signal for neutrophils to remain in BM.

The CXCL12:CXCR4 retention signal and the CXCL1/2:CXCR2 release signal regulate neutrophil numbers in BM in two key sites: the vasculature endothelium (which secretes the highest concentrations of CXCL1 and CXCL2) and the BM stroma (which is where the majority of CXCL12 is produced) (Day and Link, 2012). Steady-state conditions favor retention signals, allowing for large stores of neutrophils to remain within the marrow. Utilizing CXCR2 knockout, CXCR4 knockout and double knockout mice, it was shown that CXCR4 signaling is more dominant than CXCR2 signaling (Eash *et al.*, 2010, 2009). However, *in vitro* treatment of neutrophils with CXCL1 or CXCL2 results in downregulation of cell surface CXCR4 (Eash *et al.*, 2009; Richardson *et al.*, 2003; Suratt *et al.*, 2004). Therefore, enough CXCL1 or CXCL2 to significantly reduce CXCR4 expression on neutrophils favor neutrophil release from BM.

G-CSF signaling, under both steady-state conditions and in response to therapeutic treatment, also sways the balance in favor of release by regulating CXCL12:CXCR4 signaling. As noted earlier, G-CSF under steady-state conditions and following therapeutic treatment is known to directly regulate the function of CXCL12 by inducing proteolytic cleavage and by indirectly regulating CXCL12 secretion by osteoblasts (Christopher and Link, 2008; Semerad *et al.*, 2005). G-CSF treatment *in vitro* and *in vivo* is associated with downregulation

of neutrophil CXCR4 (De La Luz Sierra *et al.*, 2007). This is accomplished by G-CSF signal-dependent production of the transcription factor Gfi-1, a zinc-finger protein that binds a DNA sequence upstream of the *Cxcr4* gene and represses expression of CXCR4. Thus, another way in which G-CSF regulates neutrophil numbers in the periphery is through regulation of neutrophil release from the BM.

Once neutrophils exit the BM, they move into the peripheral blood where they may remain until they become senescent or spontaneously apoptose or they may move into a secondary site to perform their innate immune function and die. When neutrophils become senescent or spontaneously apoptose, they are primarily cleared in BM, liver, and spleen (Furze and Rankin, 2008a,b; Suratt *et al.*, 2001; Thakur *et al.*, 1977). It is believed that homeostatic CXCL12 expression in these tissues attracts neutrophils. However, when the neutrophil exit the BM and enter the peripheral blood, CXCR4 expression is downregulated or the receptor has been cleaved off the cell surface (Gordy *et al.*, 2011; Kim *et al.*, 2006; Levesque *et al.*, 2003, 2003; Martin *et al.*, 2003; Nagase *et al.*, 2002). So then how are neutrophils attracted to these tissue sites? Freshly isolated neutrophils lack CXCR4 expression on the cell surface, but after 20 h in culture, this expression increases suggesting that as neutrophils age CXCR4 levels increase (Martin *et al.*, 2003; Nagase *et al.*, 2002). How and whether this occurs under physiological conditions remains unclear.

Once older or senescent neutrophils home into tissue sites, they undergo apoptosis. Apoptotic neutrophils are then phagocytosed by tissue phagocytes (e.g., macrophages, Kupffer cells, and dendritic cells) usually found within the reticular endothelial system. These phagocytes are in direct contact with the blood for better recognition of apoptotic/senescent neutrophils (Furze and Rankin, 2008a,b; Gordy *et al.*, 2011; Suratt *et al.*, 2001). It is hypothesized that the process of engulfing apoptotic neutrophils curbs further production/release of new neutrophils. Macrophages and dendritic cells produce IL-23 which can stimulate $\gamma\delta$ T cells, natural killer (NK) T cells, and Th17 cells to produce IL-17 (Aggarwal *et al.*, 2003). IL-17 stabilizes G-CSF mRNA by increasing its half-life, ultimately enhancing systemic concentrations of G-CSF and driving granulopoiesis and release of neutrophils into the peripheral blood (Cai *et al.*, 1998). However, several papers dispute these findings suggesting that it may be an artifact of the mouse model used or may only occur following stress/inflammation. These latter papers describe a process that does not involve IL-23 or IL-17 (Furze and Rankin, 2008a,b; Gordy *et al.*, 2011). Rather, the data suggest that in BM and spleen, absence of phagocytosis of apoptotic neutrophils results in production of G-CSF, IL-1 β , and CCL3 (MIP-1 α) in an IL-17-independent manner. Further experiments utilized a mouse model that lacked marginal zone and BM stromal macrophages. These mice exhibited neutrophilia that was G-CSF-dependent and IL-1 β and CCL3-independent (Gordy *et al.*, 2011). Mechanisms regulating G-CSF expression are not clear. Thus, under steady-state conditions, circulating neutrophil numbers, as well as new neutrophil production in BM, may be regulated by numbers of apoptotic/senescent neutrophils being phagocytosed by tissue phagocytes in BM, spleen and liver and alterations to the chemokine/cytokine milieu that this process creates.

Role of CXCL12 in Maintenance of the B cell Lineage in BM

Development of lymphoid cells or lymphopoiesis is regulated by CXCL12. CXCL12^{-/-} or CXCR4^{-/-} mice demonstrate reduced B cell lymphopoiesis in the fetal livers and an almost complete loss of lymphopoiesis in BM (Kawabata *et al.*, 1999; Ma *et al.*, 1998, 1999; Nagasawa *et al.*, 1996; Zou *et al.*, 1998). Transplantation of CXCL12 or CXCR4 knockout fetal liver cells into lethally irradiated wild type mice led to greatly reduced reconstitution of adult BM B cells (Kawabata *et al.*, 1999; Ma *et al.*, 1999). These transplanted mice also exhibited increased numbers of B cell precursors in the bloodstream suggesting that CXCL12:CXCR4 signaling is required for retaining B cell precursors within the BM (Ma *et al.*, 1999).

It was discovered that like HSCs, early lymphoid progenitors had preferred niches within the BM (Ding and Morrison, 2013; Greenbaum *et al.*, 2013). Upon deleting *Cxcl12* from osteoblasts, using a Col2.3-*cre* mouse model, there was a modest loss in common lymphoid progenitor cells (CLPs). The importance of the osteoblast lineage in lymphopoiesis was further explored by deleting *Cxcl12* in osteoprogenitor cells utilizing the Osterix-*cre* mouse model. Lack of CXCL12 expression in osteoprogenitor cells led to a significant loss of B lymphoid progenitors and B cell precursors, suggesting that the osteoblast lineage plays a role in B cell lymphopoiesis. This is further supported by early lymphoid progenitors accumulating near the endosteum (Ding and Morrison, 2013). Deletion of CAR cells, an adipo-osteogenic progenitor, led to reduced frequency of CLPs in BM (Omatsu *et al.*, 2010). In addition, deletion of *Cxcl12* from perivascular MSPCs, utilizing the Prx1-*cre* mouse model, also led to significant reduction in lymphoid progenitors. However, deleting *Cxcl12* from endothelial cells, utilizing the Tie2-*cre* mouse model, resulted in unaltered committed lymphoid phenotype. This suggested that MSPCs, osteoprogenitor cells, and to lesser extent osteoblasts play roles in lymphoid lineage maintenance, but endothelial cells do not (Ding and Morrison, 2013). Thus, early lymphoid progenitors, in particular those of the B cell lineage, prefer the endosteal niche. The close proximity of CLP and B cell precursors to niche cells allows these cells to be in a microenvironment that provides essential growth factors for B cell differentiation and proliferation such as IL-7, insulin-like growth factor 1, SCF, and FLT-3 amongst others (D'Apuzzo *et al.*, 1997; Dorshkind *et al.*, 1992; Kincade, 1992).

CXCL12:CXCR4 signaling is an important BM retention signal for B cell precursors. As mentioned above, HSC/HPC and neutrophils rely on altered CXCL12/CXCR4 expression to help determine whether to remain within the BM. Unlike neutrophils, whose CXCR4 expression is downregulated or lost when the cell matures, allowing for its migration out of the BM, immature and naïve B cells that need to migrate out of the BM do not have reduced CXCR4 expression compared to CLP or B cell precursors (Glodek *et al.*, 2003; Stein and Nombela-Arrieta, 2005). Instead, B cell precursors and immature/naïve B cells alter the intensity of VLA-4:VCAM-1 adhesion to stromal cells by regulating the duration of activation of downstream signaling molecules within the CXCL12:CXCR4 signaling pathway. Upon CXCL12:CXCR4 signaling,

focal adhesion kinase (FAK), an important regulator of cell adhesion and migration, is activated by phosphorylation which occurs in a PI3-K- and PKC-dependent process (Glodek *et al.*, 2003). However, the duration of this phosphorylation event is longer in B cell progenitors than in their more mature counterparts. As progenitor B cells differentiate into a more mature phenotype, CXCL12 responsiveness overtime diminishes, causing loss of the sustained adhesion response to stroma cells, thus allowing more mature B cell to migrate out of the BM (Glodek *et al.*, 2003).

Once having migrated into the periphery, B cells undergo antigen-driven differentiation into antibody-secreting cells (ASCs) in peripheral lymphoid tissue (e.g., lymph nodes). This results in downregulation of chemokine receptors that allow B cells to migrate into and be retained within peripheral lymphoid tissues. The type of antigen-driven differentiation helps regulate cell surface chemokine receptor expression. Both systemically induced IgG ASCs and IgM ASCs are found in large number within BM, as well as a small number of intestinally induced IgA ASCs, suggesting that BM is an important site for production of serum antibody responses (Kunkel and Butcher, 2003). The quantity and type of ASCs found in BM is dependent on cell expression of CXCR4 and responds to CXCL12. Intestinally induced IgA, systemically induced IgG and IgM ASCs all express CXCR4. Following immunization in mice that were transplanted with CXCR4-deficient fetal liver cells, antigen-specific ASCs were found in larger numbers in spleen and peripheral blood. This correlated with fewer ASCs within BM, suggesting that CXCR4 plays a role in the ability of ASCs to home to BM. Since there was not a complete loss of CXCR4-deficient ASCs within BM, this suggests that other chemokines/cytokines may play a role in this homing. ASCs found within peripheral blood as well as BM also express CXCR6. The ligand for CXCR6 is CXCL16 which is also expressed in BM compartment. It is important to note that the BM is not the only CXCL12-enriched tissue. Spleen and epithelium in mucosal tissue also express CXCL12, and are known to recruit ASCs. BM, as well as other CXCL12-enriched sites, provides survival signals needed for these cells to perform their function so that long lasting humoral immunity is established.

The Role of CXCL12 in Balancing Granulopoiesis and Lymphopoiesis during Inflammation

CXCL12 plays an important role in maintenance of both myeloid- and lymphoid-lineage cells within BM under homeostatic conditions, but what role does CXCL12 play in regulating granulopoiesis and lymphopoiesis following danger signals? Proinflammatory cytokines, especially tumor necrosis factor α (TNF- α) and IL-1 β , mobilize lymphocytes (e.g., T cells, B cells, and B cell progenitors) in great numbers out of the BM and into the periphery (Nagaoka *et al.*, 2000; Ueda *et al.*, 2005, 2004). Depletion of lymphocyte numbers correlate with reduction in CXCL12 expression in BM (Ueda *et al.*, 2004). This reduction in CXCL12 occurs both by reducing its expression as demonstrated through reduction in message levels, and through posttranslational mechanisms, most likely through proteolytic cleavage (Ueda *et al.*, 2004). Loss of BM lymphocytes is associated with increased extramedullary

lymphopoiesis in the spleen; however, the importance of this event is unknown (Ueda *et al.*, 2004).

Loss of B cell lymphopoiesis and reduction in lymphoid cell numbers in BM is associated with a large expansion in granulopoiesis in BM and increased neutrophil numbers in the periphery (Nagaoka *et al.*, 2000; Ueda *et al.*, 2004, 2005). Expansion of BM granulocytes appears to occur within the same niche that the lymphocytes abandoned. Under homeostatic conditions, granulopoiesis and lymphopoiesis are balanced by a sufficient supply of growth resources that are shared in both processes. The importance of increasing granulopoiesis during inflammation is high since once neutrophils exit the BM its lifespan in the periphery is only hours to days; therefore, it is essential that during inflammation, the equilibrium in the BM should initially shift in favor of granulopoiesis. However, it is also important that the equilibrium between granulopoiesis and lymphopoiesis be re-established following inflammation. Normal lymphoid numbers in the BM following resolution of inflammation corresponds to reduced IL-1 β expression and overexpression of lymphoid growth factors, suggesting that the shared granulocyte and lymphoid niche may require a bias toward lymphopoiesis to reverse increased granulopoiesis.

If CXCL12-depleted mice demonstrate loss of both myeloid and B cell progenitors, why when CXCL12 concentrations are reduced in the BM following inflammation do we observe a loss of lymphopoiesis but an increase in granulopoiesis? One hypothesis is that myeloid progenitors are more sensitive to smaller concentrations of CXCL12 than lymphoid progenitors. Several studies support this rationale. First, CXCL12 is still present in BM following exposure of mice to TNF- α and IL-1 β ; however, it is reduced when compared to normal levels. Second, depleting CXCL12 production from one hematopoietic niche cell at a time was insufficient to reduce myeloid progenitors. Depleting either osteoprogenitor cells or osteoblasts was sufficient to reduce CLP and B cell precursor numbers. Another possibility is that there is another retention signal that works synergistically with lower levels of CXCL12 to help maintain myeloid progenitors in the BM.

Conclusion

CXCL12:CXCR4 signaling is important in maintaining HSC, HPC, and mature leukocyte numbers in the BM and in the periphery. Investigating the role of this key chemokine in the BM microenvironment is essential to understanding hematopoiesis. Not only is this important in discovering new options for enhancing engraftment of HSCs and HPCs or in enhancing numbers of mobilized HSCs and HPCs to collect for transplantation, but also for understanding how leukocyte numbers in the periphery are regulated. By better understanding these processes, it is possible that new therapeutics can be developed for treating different types of blood disorders as well as infection and tissue injury.

Glossary

Antigen Molecules that can elicit an immune response.

Antigen presentation The display of peptides bound to major histocompatibility complex on the surface of an antigen presenting or target cell, permitting specific recognition by T cells and their activation.

Co-inhibitory molecule A molecule on the surface of an antigen presenting or target cell that provides a negative signal for the antigen-specific activation of T cells.

Co-stimulatory molecule A molecule on the surface of an antigen presenting or target cell that provides a positive signal for the antigen-specific activation of T cells.

Diapedesis The process by which a cell breaches and migrates across an endothelial barrier in order to either exit or enter the blood circulation.

Immune surveillance The process of the immune cells moving throughout the body in search of invading pathogens and aberrant (e.g., cancerous) host cells.

Immunological synapse (IS) Interface between a lymphocyte and an antigen-presenting cell responsible for coordination of antigen recognition and response.

Intravasation The process through which a cell (leukocytes and cancer cells) breaches the basal lamina of the endothelium from the interstitium into the lumen of a blood or lymphatic vessel, in order to enter the circulation.

Invadopodia Cylindrical cellular structures with an actin-rich core that establish close contact with the extracellular matrix (ECM), typically formed in cancer cells. Invadopodia have a diameter of approximately 8 μm and a height of approximately 5 μm , they are very stable and are associated with matrix degradation.

Invadosomes Term including both podosomes and invadopodia.

Invadosome-like protrusions (ILPs) Submicron-scale, actin-rich cylindrical protrusions related to invadosomes through which lymphocytes actively probe the surface of the endothelium by dynamic insertion and retraction. These were demonstrated to function in supporting migratory pathfinding and to enforce close T cell–EC apposition, which seems to facilitate Ag recognition and TCR signaling.

Major histocompatibility complex (MHC) Surface molecules involved in the process of antigen presentation.

Podosome Highly dynamic cylindrical cellular structures with an actin-rich core that establish close contact with the ECM, typically formed in monocytic cells (monocytes, macrophages, dendritic cells, and osteoclasts), endothelial cells, and smooth muscle cells. Podosomes have a diameter of approximately 1 μm and a height of approximately 0.4 μm .

Podo-prints Endothelial invaginations generated by protrusion of lymphocyte ILPs.

Podo-synapse A novel IS architecture dominated by dense arrays of calcium-stabilized ILPs.

Secondary lymphoid organs (SLOs) SLOs include lymph nodes, tonsils, spleen, Peyer's patches, and mucosa-associated lymphoid tissue (MALT). These serve as locations for lymphocytes become in contact with the antigen to initiate and regulate adaptive immune responses.

T cell receptor T cell surface molecule that recognizes the antigen in the context of MHC.

Introduction

The endothelia of the contiguous vascular and lymphatic circulatory systems form the essential barrier that partitions the body's most fundamental compartments: the tissues and the blood/lymph. Immune cells have the mandate to continuously move throughout the body and pass in and out of the tissues in order to conduct immune surveillance and mediate immune responses. The basic barrier versus invasive functions of endothelial and immune cells, respectively, would seem to be fundamentally opposed. However, highly cooperative interactions between these cell types promote extremely efficient immune cell trafficking and surveillance while retaining barrier functions. The nature of this cooperation seems to be deeply rooted in evolutionary and developmental origins. Indeed, the first appearance of both a closed endothelial-lined circulatory system (Monahan-Earley *et al.*, 2013) and of an adaptive immune system (Bajoghli *et al.*, 2009;

Kasahara and Sutoh, 2014; Hirano *et al.*, 2011) occurred simultaneously ~500 million years ago in the ancestors of the most phylogenetically distant living vertebrates from mammals, lampreys, and hagfish. Additionally, in mammalian development both endothelial and hematopoietic lineages derive from a common hemangioblast precursor (Choi *et al.*, 1998; Lancrin *et al.*, 2009; Risau and Flamme, 1995; Tavian *et al.*, 2000), which would seem to underlie the unique multitasking ability of the endothelium to function as both a barrier and an antigen-presenting cell (APC). In this article we provide an overview of the architecture of the vascular and lymphatic circulation, as well as the basic contexts and mechanisms for lymphocyte–endothelial interactions during trafficking. After establishing this background, we summarize the known functional contributions of endothelial cells (ECs) to antigen (Ag)-dependent regulation of adaptive immunity and the unique cellular and molecular mechanisms involved in this information exchange.

The Endothelium as a Barrier for the Vascular and Lymphatic Systems

Vascular Endothelium

The vascular endothelium is an anatomically unique structure. A defining feature of higher multicellular organisms is the presence of a closed cardiovascular circulatory system that delivers oxygen and nutrient-rich blood to the tissues (Monahan-Earley *et al.*, 2013). This system is organized as a series of large arterial vessels (macrovascular) that carry blood away from the heart and progressively branch into smaller diameter

arteriole vessels and ultimately capillaries in which oxygen and nutrient exchange occurs (Figure 1). Further downstream, individual capillaries merge into progressively larger post-capillary venules and veins that eventually return to the heart (Figure 1). The vascular endothelium is the monolayer of cells (blood endothelial cells; BECs) that form the inner lining of this circulatory system and distinctly serves as the physical barrier that maintains organization between the blood and tissue compartments.

Altogether the blood vasculature is an enormous organ system that is comprised of ~60 trillion BECs, that make up

Figure 1 Blood-lymph circulatory system schematic depicts the contiguous blood-lymph circulatory system. Arterial, oxygen-rich, blood (pink) flows away from the heart into the microvasculature (arterioles, capillaries, and venules). Oxygen-depleted blood (blue) flows away from the microvasculature back to the heart. Fluid (lymph; green) leaked into the tissue (yellow) from the microvasculature is taken up by the lymphatic capillaries, and progressively flows through the afferent lymphatic vessels, LNs, efferent vessels, and back into the blood circulation via the lymphatic duct. Local microvasculature of the lymph node (i.e., high endothelial venules (HEV)) serves as a location for lymphocytes to enter the LN. Dark pink and dark green lines indicate the vascular and lymphatic endothelial barriers, respectively. Boxed region (lower panels) depicts a segment of postcapillary venule (right) and the fundamental composition of the minimal endothelial barrier unit: an endothelial cell monolayer; intercellular adhesions, adhesions to the basement membrane.

~165 000 km of vessels with a total surface area of ~4000–7000 m² (most of which are the microvascular vessels; i.e., arterioles, capillaries, and venules) (Aird, 2005; Hwa *et al.*, 2005). The overall architecture of the blood vasculature is such that microvessels are densely interdigitated throughout all other tissues and organs of the body. As a result, most tissue cells lie within just tens of microns of a vessel. This allows for highly effective delivery of oxygen and nutrients (Aird, 2007a,b). An additional consequence of this design is that every tissue microenvironment has a local interface (i.e., BECs) with the circulation. As we discuss below, evolution has apparently taken advantage of this arrangement to provide BECs with effective ‘sentinel’ functions that are able to communicate local interstitial information (e.g., infection, damage) directly to circulating immune cells in circulation.

Lymphatic Endothelium

The blood circulatory system works in concert with an adjunct lymphatic system. Rather than forming a closed circulation, the lymphatic vessels begin blindly in the intercellular spaces of the soft tissue (not unlike the roots of a tree) in close proximity to microvascular beds (Figure 1; Girard *et al.*, 2012). Such ‘terminal lymphatic capillaries’ progressively merge to form afferent collecting vessels that feed into lymph nodes (secondary lymphoid tissues that receives antigens from lymph), which are connected downstream to efferent lymphatic vessels. These merge into larger collecting vessels and ultimately the thoracic duct that connects directly to the venous blood circulation at the subclavian vein (Figure 1). The lymphatic system serves to collect fluids (lymph fluid), which leak from capillaries into the tissue, and return them back to the vascular circulation. This is required to maintain an appropriate interstitial fluid balance. In addition, the lymphatics provide a route for trafficking of interstitial APCs (e.g., dendritic cells; DCs) to lymph nodes (Girard *et al.*, 2012; Figure 1). As with the blood circulation, the lymphatic system is also lined by a monolayer of lymphatic endothelial cells (LECs) that provide the barrier that separates the tissue from the lymph.

Basic Features of Endothelia

LECs and BECs are highly similar in many regards, yet also exhibit important phenotypic and functional distinctions (Aird, 2007a,b; Pfeiffer *et al.*, 2008). Moreover, significant heterogeneity is found among ECs based on the size of a vessel and the tissue in which they reside (Aird, 2007a,b). Nonetheless, the minimal barrier unit of all endothelia fundamentally consist of a monolayer of endothelial cells that are held to each other by adherens and tight junction proteins (e.g., VE-cadherin, platelet endothelial cell adhesion molecule-1 (PECAM-1), junctional adhesion molecule (JAM-1), CD99, claudins, and occludins) and to the underlying basement membrane by integrin adhesion receptors (e.g., $\alpha\beta3$ and $\alpha5\beta1$) (Bazzoni and Dejana, 2004; Pepper and Skobe, 2003; Baluk *et al.*, 2007; Figure 1).

Contexts for Lymphocyte–Endothelial Interactions

In order to conduct their basic function of searching for pathogens to eliminate, immune cells must continuously traffic throughout the body (von Andrian and Mackay, 2000). While movement within the vascular circulation and lymphatic systems provides a means of rapid and organized transit, immune cells must also repeatedly move in and out of the tissues by adhering to and migrating across the BEC and LEC barriers (a process known as ‘transendothelial migration’ or ‘diapedesis’) (Ley *et al.*, 2007; von Andrian and Mackay, 2000). Before we discuss the mechanisms driving immune cell adhesion and diapedesis, we will first consider the diverse contexts for such events, focusing on just one subtype of immune cell, the T lymphocyte (or T cell).

T Lymphocytes Defined

T lymphocytes are a branch of the adaptive immune system, which are able to detect the presence of infecting pathogens (e.g., virus or bacteria) or aberrant host cells (e.g., tumor cells) by identifying unique molecular features that distinguish them from the host (termed foreign Ag). Specifically, these Ag are derived from protein fragments (i.e., ‘peptide Ag’) and recognized by specialized cell-surface T cell receptors (TCRs). Importantly, peptide Ag can only be detected when presented on the surface of an APC by major histocompatibility complex (MHC) proteins (Schwartz, 1992; Germain, 1994). T cells that have never encountered their specific cognate Ag are termed ‘naïve.’ Those that have been activated by Ag become either ‘effector cells’ that participate actively in immune responses to eradicate the detected pathogen or long-lived ‘memory’ cells that serve as the basis for ‘acquired’ or ‘adaptive’ immunity. Additionally, two major kinds of T cells exist. Those that bear the cell surface marker CD4 only respond to Ag presented on class II MHC molecules (MHC-II) and participate in immune reactions to exogenous antigens, mostly through secretion of cytokines that ‘help’ other immune cells to conduct their functions (termed ‘CD4 T helper or Th cells’) (Schwartz, 1992; Germain, 1994). Those that bear CD8 respond to endogenously produced Ag presented on MHC-I and function in direct killing of Ag bearing cells (termed ‘CD8 T cells’ or ‘cytotoxic T cells’; CTL) (Schwartz, 1992; Germain, 1994).

Trafficking during T Lymphocyte Maturation

The life cycle of all immune cells starts in the bone marrow. In the case of T lymphocytes, immature T cell progenitors first cross the bone marrow sinusoidal endothelium in order to enter the blood stream (i.e., intravasate) (De Bruyn *et al.*, 1971; Chamberlain and Lichtman, 1978; Wolosewick, 1984; Figure 2). These immediately home to the thymus where they exit the blood circulation (i.e., extravasate) (Figure 2) via diapedesis across the thymic postcapillary vessels in order to enter the thymus. Here, strongly self-reactive cells are deleted and weakly self-reactive ones mature. Weak self-reactivity generates a repertoire of mature T cells that generally do not become activated in response to self-antigens and have a possibility of reacting to foreign antigen on self-MHC proteins.

Figure 2 Stages of lymphocyte trafficking across endothelial barriers: Intravasation and extravasation trafficking of lymphocytes throughout the body requires their movement out of (intravasation) and into (extravasation) the tissue. Upper Panel: Stages of intravasation. The details of the process by which lymphocytes (blue) enter vascular and lymphatic structures are not well characterized, but generally characterized to involve steps of interstitial migration toward the vessel, migration (sometimes long-range) on the basal-lateral side of the endothelium, migration across the basement membrane and endothelial barriers (diapedesis), and ultimately, entry of lymphocytes into the blood vessel lumen and the circulation. Lower Panel: Stages of extravasation. The lymphocyte extravasation process has been intensively studied and shown to involve, in the first instance, transient rolling-type interactions mediated predominantly by selectins. This facilitates chemokine-dependent activation and firm arrest, which is mediated by the binding of leukocyte integrins (e.g., LFA1, Mac1, and VLA4) to endothelial cell-adhesion molecules (e.g., ICAM1, ICAM2, and VCAM1). Subsequently, leukocytes migrate laterally over the surface of the endothelium, probing for a site to penetrate through it (see also **Figure 3**). Finally lymphocytes cross the endothelial barrier (diapedese) and enter the interstitium either by opening a gap between two adjacent endothelial cells (paracellular route) or by migrating directly through the body of a single endothelial cell (transcellular route).

A small subset of T cells with intermediate self-reactivity become regulatory T cells (Tregs). Mature naïve T lymphocytes exit the thymus via diapedesis across postcapillary venules (to reenter the blood circulation directly) or across lymphatic vessels of the thymus (to enter the lymphatic system, and eventually the blood circulation) (Toro and Olah, 1967; Ushiki, 1986; Weinreich and Hogquist, 2008; Kotani *et al.*, 1966; Ernstom *et al.*, 1965).

Trafficking during T Lymphocyte Immune Surveillance

Once in the blood, naïve T cells begin constitutive cycles of migrating into and out of secondary lymphoid organs (SLOs) in search of cognate Ag. This starts as T cells pass through specialized high endothelial (postcapillary) venules (HEVs) that constitutively expresses adhesion molecules (e.g., peripheral lymph node addressin (PNAd), ICAM-1, ICAM-2, and mucosal vascular addressin cell adhesion molecule 1 (MAdCAM-1)) and chemokines (e.g., CC chemokine ligands (CCL19 and CCL21)) necessary to promote naïve and memory

lymphocyte diapedesis (Girard *et al.*, 2012; Miyasaka and Tanaka, 2004; von Andrian and Mackay, 2000). The exception to this is the spleen, where there are no HEV and T and B cells enter through the specialized blood endothelium of the splenic marginal zone or through 'bridging channels' connecting the venous sinuses of the splenic red pulp (RP) from the SLO compartment referred to as the white pulp (WP). Once inside SLO, T cells migrate to 'T cell area' where high numbers of tissue-derived DCs are found (Bajenoff *et al.*, 2007). DCs are a type of 'professional' APC that can efficiently phagocytize extracellular material, process proteins and present peptide Ag on their surface via both MHC-I and MHC-II molecules. DCs also have a unique ability (along with LEC, see below) to ingest exogenous antigens and present them on the MHC-I, such that DCs do not need to be infected with viruses or intracellular microbes to be able to initiate activation of CD8⁺ T cells. DCs also express a wide range of 'co-stimulatory' molecules and cytokines that are also needed, together with MHC-Ag, to activate responses in naïve T cells (Schwartz, 1992; Janeway and Bottomly, 1994; Paul and Seder, 1994; Germain, 1994) (discussed further below). As T cells migrate

throughout the T cell area they form a series of short-lived intimate contacts with the DCs that allow them to survey the cell surface MHC–Ag complexes (von Andrian and Mempel, 2003). When these interactions fail to identify a cognate Ag, T cells leave the T cell area and undergo random migration within the cortical and medullary sinuses of the lymph node. During this process they mediate direct interactions with the LECs that line these sinuses. Eventually, after tens of minutes these T cells transmigrating across the LECs barrier to enter the efferent lymphatic vessels, which ultimately carry them back into the blood circulation (Figure 1; Grigorova *et al.*, 2009, 2010; Farr *et al.*, 1980; Olah and Glick, 1985).

Trafficking during T Lymphocyte Immune Responses

In cases when T cells do encounter cognate Ag on lymph node DCs, the two cells engage in sustained (~30 min to 8 h) intimate cell–cell interactions, with precisely regulated sub-cellular architecture and dynamics (Mempel *et al.*, 2004; Fooksman *et al.*, 2010). The result of such ‘immunological synapses’ (ISs) (Grakoui *et al.*, 1999) is the triggering of sustained calcium signaling in the T cells that leads to T cell activation, proliferation, and differentiation into of Ag-specific effector and memory lymphocytes (Dustin, 2003). These cells reenter the circulation now reprogrammed (e.g., with decreased CD62L and CC chemokine receptor (CCR7) and increased LFA-1, very late antigen 4 (VLA4), CCR3, CCR5, and CXCR3 expression) to adhere preferentially to, and migrate across, activated endothelia of infected/inflamed peripheral tissues (Springer, 1994; von Andrian and Mackay, 2000) (discussed further below). Of note, any tissue can become inflamed and the resident vascular beds may exhibit extensive phenotypic and functional diversity that may strongly influence the outcome of these interactions (Aird, 2007a,b).

Trafficking-Independent Interactions between T Lymphocytes and EC

In addition to the trafficking events described above, there is a range of trafficking/diapedesis-independent settings whereby T cells and ECs engage in intimate contacts. First, it must be noted that the average diameter of a lymphocyte (~8–12 μm) exceeds that of capillaries (~5–10 μm). Thus, every trip through the circulation includes a phase of extremely close T cell–endothelial cell (EC) contacts as the T cell pass through a capillary bed. In addition, emerging intravital imaging technologies have begun to reveal more sustained intra- and extravascular T cell–BEC interactions. CD4 Th1 and Th17 lymphocytes were discovered to undergo repeated transient (~20 min duration) arrest on resting liver sinusoidal endothelium (Carambia *et al.*, 2013). Certain immune cells have also been shown to undergo constitutive long-range intravascular migrations (Figure 2). Such intravascular surveillance was first noted for natural killer T cells patrolling the liver sinusoidal endothelium (Geissmann *et al.*, 2005; Velazquez *et al.*, 2008). This patrolling was arrested by exposure to glycolipid antigens, presented by CD1d, recognized by these ‘innate-like’ T cells. Subsequently, subsets of monocytes were seen to crawl continuously within noninflamed peripheral

microvasculature of the skin, mesentery, and central nervous system, apparently searching for signs of infection or damage in the underlying tissues in a form of innate patrolling (Auf-fray *et al.*, 2007; Audoy-Remus *et al.*, 2008). Recently, effector T lymphocytes were shown to undergo extended both luminal and abluminal migration on brain microvascular endothelium in the setting of autoimmune reaction (Bartholomaeus *et al.*, 2009).

Altogether the preceding discussion demonstrates that lymphocytes undergo extensive interactions with diverse endothelia. These take place at different time points during lymphocyte maturation and differentiation, each with distinct functional roles. These represent important opportunities for functional information exchange between T cells and ECs. Indeed, exquisitely sophisticated local intercellular communication between T cells and ECs exist that are central to effective immune functions, as discussed below.

Mechanisms for T Lymphocyte Adhesion to and Diapedesis across Endothelia

Molecular Basis for Adhesion and Diapedesis

Lymphocyte–endothelial interactions are essential determinants of lymphocyte trafficking. The process of lymphocyte egress from the blood into the tissues (extravasation) involves a highly orchestrated dynamics on the part of both the lymphocyte and the endothelium, as we discuss in the following section. The process of intravasation is equally important and probably shares many of the mechanisms of extravasation (Huttenlocher and Poznansky, 2008; Carman, 2009a; Wolosewick, 1984). However, since this process remains far less studied, it will not be discussed further herein.

Whether for constitutive (e.g., to thymus or SLOs) or inflammation-induced trafficking, the first active events in extravasation are the expression and cell surface presentation of adhesion molecules and chemoattractants by ECs. In response to local tissue-derived signals (e.g., cytokines), BECs present cell surface adhesion molecules including selectins (E-selectin, P-selectin), selectin ligands (PNAd), and cellular adhesion molecules (CAMs; ICAM-1, ICAM-2, VCAM-1, MAdCAM-1) (Ley *et al.*, 2007; von Andrian and Mackay, 2000). Some of these molecules, such as P-selectin, are mobilized to the cell surface from preexisting intracellular pools (i.e., specialized granules termed Weibel–Palade bodies). Others are transcriptionally upregulated. In addition, endothelial cells present chemoattractants bound the glycoproteins and glycolipids (collectively termed the glycocalyx) on their luminal surface (Proudfoot *et al.*, 2003). These may be expressed by the endothelial cells themselves (e.g., GM-CSF, Gro-regulated oncogenes (GRO- α , GRO- γ), IL-6, IL-8, monocyte chemoattractant protein (MCP-1), regulated on activation, normal T cell expressed and secreted (RANTES)) (Goebeler *et al.*, 1997; Card *et al.*, 2014) and/or be produced in the interstitium, internalized by BECs abluminally and actively transcytosed to the luminal surface (Middleton *et al.*, 1997, 2002). By creating carefully controlled local expression/presentation of the appropriate adhesion molecules and chemoattractants,

endothelia generate a type of ‘address code’ to promote adhesion and trafficking of target subsets of immune cells (Springer, 1994; von Andrian and Mackay, 2000; Butcher, 1991). As just one simple example we can consider the tissue of the gastro-intestinal tract or ‘gut’. The specific immunologic demands of this environment require specialized subsets of gut lymphocytes that uniquely express the integrin $\alpha 4\beta 7$ (Gorfu *et al.*, 2009). Only the HEVs of gut-associated lymphoid tissues or microvasculature of inflamed gut tissues express the specific ligand for $\alpha 4\beta 7$, MAdCAM, thus providing a basis for selective recruitment of the gut-specific lymphocyte subset.

Once the address code is in place (for acute inflammation this can be induced in just a few hours) a well-ordered series of events take place (Butcher, 1991; Springer, 1994; Luscinskas *et al.*, 1994; Ley *et al.*, 2007; Figure 2). This process begins with transient rolling type adhesions mediated by the selectin family of adhesion molecules binding to their glycoprotein/glycolipid ligands (Step 1). The resulting increase in cell–cell contacts facilitates T cell sensing of chemokines presented on the endothelial surface, which induces intracellular signaling and ‘activation’ responses (Step 2). This, in turn, triggers high affinity interaction of lymphocyte integrin adhesion receptors (e.g., LFA-1, Mac-1, and VLA-4) with their endothelial ligands (e.g., ICAM-1, ICAM-2, and VCAM-1) resulting in firm lymphocyte arrest (Step 3) (Luo *et al.*, 2007). Subsequently, lymphocytes undergo actin-dependent spreading, polarization and integrin/CAM-dependent lateral migration over the luminal surface of the endothelium (covering tens of microns over several minutes) (Step 4). This activity seems to allow lymphocytes to search out sites permissive for endothelial barrier penetration (Schenkel *et al.*, 2004; Phillipson *et al.*, 2006). Finally, the lymphocyte formally breaches the endothelium either at the intercellular junctions (i.e., para-cellularly) or directly through individual endothelial cells (i.e., the ‘trans-cellular route’) (Step 5) (Muller, 2003; Sage and Carman, 2009; Ley *et al.*, 2007; Figure 2). In addition to integrins and CAM ligands, other adhesion molecules (e.g., PECAM-1, JAM-1, and CD99) also contribute to Step 5.

Specialized Cytoskeletal Remodeling during Adhesion and Diapedesis

During the above cascade avid cytoskeletal remodeling takes place in both the lymphocyte and the endothelium. These act in concert to create more intimate interactions and ultimately guide the process of diapedesis while preserving endothelial barrier properties.

Endothelial remodeling: Docking, guidance and barrier maintenance

In response to lymphocyte adhesion, the endothelium rapidly assembles F-actin-rich microvilli-like structures at the site of T cell attachment (Barreiro *et al.*, 2002; Carman *et al.*, 2003; Carman and Springer, 2004; Carman, 2009b). These form as a consequence of direct ligation and clustering of ICAM-1 and VCAM-1 by lymphocyte integrins, which triggers signaling to the actin adaptor/regulatory proteins, ezrin and moesin (Barreiro *et al.*, 2002). During rapid lateral T cell migration, these microvilli contacts serve as tethers at the trailing edge of the

lymphocyte to encourage lateral migration arrest (Carman and Springer, 2004). As lymphocytes slow their lateral migration, large assemblies of microvilli form symmetrically around the T cells that effectively embrace them, termed ‘docking structures’ or ‘transmigratory-cups’ (Barreiro *et al.*, 2002; Carman and Springer, 2004). The resulting increase in cell–cell contact area (which is enriched endothelial ICAM-1 and VCAM-1 and lymphocyte LFA-1 and VLA-4 integrins) promotes adhesion strengthening to better resist T cell detachment by fluid shear forces of the circulation. This structure also provides a traction scaffold that is oriented perpendicular to the plane of the endothelium (i.e., parallel to the ultimate plane of diapedesis) that functionally guides T cells to breach and migrate across the endothelial barrier (Carman, 2009b; Figure 3). At the same time, this architecture helps to meet the need for functional barrier maintenance. Though significant size ($\sim 4\text{--}6\ \mu\text{m}$) pores and gaps must form in the endothelial barrier, which serve as passageways that accommodate diapedesis, the transmigratory cup maintains extensive close cell–cell contacts that minimize leakage of blood fluids or proteins during the diapedesis event. At the final conclusion of diapedesis (which is typically several minutes after the process began) the lymphocyte ultimately exits the migration passageway. At this point, the endothelium rapidly mobilizes a distinct type of Rac-1- and Arp2/3-dependent actin remodeling activity (termed ‘ventral lamellipodia’), which serve the specialized role of rapidly resealing the barrier (Martinelli *et al.*, 2013). Thus, endothelial cells actively support and guide lymphocyte egress across it while maintaining barrier integrity through actin remodeling dynamics and intimate adhesions.

T Lymphocyte remodeling: Spreading, migration, probing, and piercing

Concomitant with the above endothelial remodeling, T cells engage in their own complex cytoskeletal and shape-change dynamics. Shortly following initial arrest, the actin cortex of the T cell breaks down in favor of Arp2/3-mediated lamellipodia. These initially radiate outward symmetrically and then rapidly (within tens of seconds) polarized into a single leading edge. Commensurate with the appearance of lamellipodia is the formation of orthogonal F-actin assemblies termed invadosome-like protrusions (ILPs) (Carman *et al.*, 2007; Carman, 2009a; Shulman *et al.*, 2009; Gerard *et al.*, 2009) that are highly related to podosomes and invadopodia found in other cells types (Linder, 2009). Each ILP is a cylindrically-shaped column of F-actin with both depth and diameter each of $\sim 0.5\text{--}1\ \mu\text{m}$. These protrude from the bottom of the T cells and exert physical forces against the endothelium that promote extremely intimate cell–cell contacts and drive deformation/indentations in the endothelial cell surface (termed ‘podo-prints’) (Carman *et al.*, 2007). ILPs are enriched in, and dependent on, LFA-1, the actin regulatory proteins WAS protein (WASp) and HS1 (a hematopoietic homolog of cortactin) and src kinase (Carman, 2009a). During lateral migration, T cells extend dozens of ILPs (preferentially near the leading edge) against the endothelia surface that dynamically turnover, each with lifetimes of $\sim 20\ \text{s}$. In this way the lymphocytes are able to physically probe or ‘palpate’ the local biomechanical properties, specifically the stiffness, of the endothelial substrate (Figure 3). Such ‘biomechanical scanning’ facilitates

Figure 3 Dynamic remodeling in endothelium and lymphocytes during diapedesis. Schematic depicts EC (pink) and lymphocyte (blue) dynamics during T cell lateral migration over and transcellular diapedesis across the endothelium. Numbered frames show successive time points that are intended to represent intervals of ~30–60 s. Dynamic insertion (~0.2–1 μm in depth) and retraction of multiple lymphocyte ILPs into the apical surface of the endothelium, is shown during lateral migration in frames 1–2. ILPs that form over the nucleus of the endothelial cell are impeded by physical resistance from the nuclear lamina and remain shallow (blue arrowheads in frame 2). At a location of sufficiently low endothelial resistance, an ILP progressively extends several micrometers in depth, ultimately breaching the endothelium transcellularly (red arrowheads in panels 2–4). Also shown is the previously described ‘trans migratory cup’ structure (asterisks), which consists of vertical endothelial microvilli-like projections (rich in F-actin; green), ICAM1, VCAM1, PECAM1, and JAM1 that surround the periphery of adherent lymphocytes. During rapid T cell lateral migration the projections serve largely as tethers to slow lymphocyte migration (orange asterisks). At later stages this structure serves to guide diapedesis by providing a vertical traction substrate for the protrusion of leukocytes against the endothelial surface (blue asterisks). As the lymphocyte exits the transmigration passageway, endothelial cells mobilize ‘ventral lamellipodia’ (purple asterisks) that rapidly restore endothelial barrier integrity.

identification of sufficiently soft EC regions, perhaps also sensing the underlying basement membrane, at which to initiate diapedesis, where ILPs can progressively extend and formally breach the endothelial barrier (Carman *et al.*, 2007; Martinelli *et al.*, 2014). Thus, lymphocytes use ILPs to guide an active process of seeking out the path-of-least-physical-resistance for egress into the tissue (termed ‘tender-taxis’) (Martinelli *et al.*, 2014). Lymphocytes from patients with the genetic immune-deficiency known as Wiskott–Aldrich syndrome (WAS), lack WASp and are unable to effectively form ILPs, which results in defective tender-taxis and diapedesis (Carman *et al.*, 2007).

Additionally, studies suggest that the intimate contacts generated by ILPs may facilitate lymphocytes’ ability to detect discrete pools of chemokine held deeply beneath the thick glycocalyx close to the endothelial plasma membrane (Shulman *et al.*, 2012). Thus, lymphocyte ILPs may function in both biomechanical and biochemical probing of the endothelial surface (as discussed further below). Importantly, such structures form in essentially every type of lymphocyte–endothelial interaction setting (e.g., bone marrow, thymus, HEVs, SLOs, and diverse inflamed tissues), including both intravasation and extravasation events (Sage and Carman, 2009; De Bruyn *et al.*, 1971; Becker and De Bruyn, 1976; Farr *et al.*, 1980; Azzali

Figure 4 Endothelial cells: A peripheral ‘semi-professional’ APC compartment. While priming of naïve T lymphocytes occurs within SLO, such as LN, by professional APCs (e.g., DC; left panel), they then egress into the peripheral circulation and diapedese into inflamed tissues to interact with interstitial APCs and targets (middle and right panels). This progression requires direct, intimate interactions with the vascular endothelium. The endothelium is established as a ‘semi-professional’ APC (see Figure 5). Thus the first peripheral APC that lymphocytes are likely to encounter after leaving SLO are endothelial cells.

et al., 2008; Barron *et al.*, 1974; Astrom *et al.*, 1968; Lossinsky and Shivers, 2004; Raine *et al.*, 1990; Fujita *et al.*, 1991; Wolosewick, 1984; Wolburg *et al.*, 2005; Olah and Glick, 1985; Greenwood *et al.*, 1994; Bamforth *et al.*, 1997; De Bruyn *et al.*, 1989). This would suggest that ILPs represent an important sensory organelle that is broadly used by lymphocytes during their trafficking to probe their local cellular environment.

Information Exchange at the T Lymphocyte–Endothelial Interface

While the endothelium clearly plays an essential role (both by delivering biochemical signals and by actively remodeling) in driving appropriate immune cell migration, the same and/or additional endothelial cues can instruct immune cell activation and differentiation states. Indeed, studies with a wide range of innate and adaptive immune cells have collectively established that diapedesis across inflamed endothelium generally has a pro-inflammatory or ‘priming’ effect on these cells (Nourshargh and Marelli-Berg, 2005). For example, effector functions of neutrophils (e.g., degranulation and respiratory burst) and APC functions of monocytes and DCs (e.g., MHC-II expression) are both upregulated by extravasation *in vivo*, as well as by diapedesis across activated endothelia *in vitro*. Such studies suggest that the endothelium communicates to immune cells, in specific ways, that they are entering a new environment and helps them to adapt their differentiation and activation states to be prepared for this new setting.

Endothelial Function in Antigen-Specific Immunity

An important, but still incompletely understood, mode of EC communication with immune cells includes Ag-specific instruction of T lymphocytes through APC function. As discussed above, activation of initial responses in naïve T cells occurs in the T cell area of the lymph node (LN) through interactions with professional APCs (i.e., DCs). DCs not only efficiently take up, process and present Ag on MHC-I and -II (‘signal 1’), but also provide a wide range of potent co-stimulatory and co-

inhibitory molecules (that bind cognate receptors on the T cell; ‘signal 2’) and secrete critical cytokines (‘signal 3’). The appropriate combination of all three of these inputs are required to activate naïve T cells (Schwartz, 1992; Janeway and Bottomly, 1994; Paul and Seder, 1994; Germain, 1994; Guermontprez *et al.*, 2002). The quality of these signals shapes the strength and type of responses generated (e.g., pro-inflammatory Th1 versus anti-inflammatory/tolerogenic CD4 Treg). Once expanded and primed, effectors T cells reenter the circulation to home to peripheral sites of inflammation in search of cognate Ag on interstitial APCs and targets (Figure 4). Thus an obligate preceding step of the effector T cell is the adhesion to and diapedesis across the endothelium. As described below, ECs are now recognized as a type of ‘semi-professional’ APCs that might exert peripheral regulation over adaptive immunity at this stage.

Antigen presenting properties of endothelial cells

Like most cells, ECs constitutively express class I MHC molecules. Additionally, they also constitutively express MHC II, which are generally restricted to professional APCs (e.g., DCs) (Choi *et al.*, 2004; Pober *et al.*, 1983). Inflammatory cytokines further upregulate MHC I and II on endothelium (Choi *et al.*, 2004). Moreover, endothelial cells express Ag processing machinery (e.g., LMP2, 7, transporter associated with antigen processing 1 (TAP1), 2, invariant chain and HLA-DM) and have been shown to efficiently take up, process and present/cross-present Ag *in vitro* and *in vivo* (Greening *et al.*, 2003; Savage *et al.*, 1995; Vora *et al.*, 1994; von Oppen *et al.*, 2009; Schurich *et al.*, 2009; Limmer *et al.*, 2000; Hirose *et al.*, 2014). Additionally, ECs express a range of co-stimulatory (e.g., ICAM-1, VCAM-1, CD40, LFA3, ICOSL, 4-1BB, OX40L, TL1A) and co-inhibitory (e.g., programmed death ligand-1 (PD-L1, PD-L2)) molecules, as well as cytokines, both of which are strongly modulated by inflammatory cues (Choi *et al.*, 2004; Hollenbaugh *et al.*, 1995; Grabie *et al.*, 2007; Rodig *et al.*, 2003; Eppihimer *et al.*, 2002; Card *et al.*, 2014; Figure 5). Critically, however, ECs generally do not express CD80 (murine B7-1) or CD86 (B7-2) co-stimulators expressed by professional APCs that are necessary for activation of naïve lymphocytes (Figure 5). As a result, ECs are incapable of activating naïve

Figure 5 Endothelial cells are 'semi-professional' APCs, schematic depicts comparison of the Ag presentation, co-stimulatory, co-inhibitory and adhesion molecules expressed by DCs and ECs. Note that endothelial cells, unlike most other non-hematopoietic cells, express most of the critical molecules found in DCs. The notable exceptions include CD80 and CD86 that are critical for activation of naive T cells, as well as the co-stimulatory/adhesion molecules DC-SIGN.

lymphocytes. However, they can readily mediate Ag-specific stimulation of Ag-experienced (i.e., effector/memory) CD4 and CD8 lymphocytes and are therefore regarded as 'semi-professional' APCs (Marelli-Berg *et al.*, 1996; Ma and Pober, 1998; Perez *et al.*, 1998; Epperson and Pober, 1994; Dengler and Pober, 2000; Sage *et al.*, 2012).

Emerging and Putative Roles for Endothelial Cell Ag Presentation

The overall functions of ECs in Ag-specific immunity remain to be completely elucidated. Clearly, such functions will be ancillary to those of professional APCs (Choi *et al.*, 2004; Pober

and Sessa, 2007). Yet, the large collective surface area of the BEC-APC compartment of $\sim 6000 \text{ m}^2$ (which, in fact, outnumbers the professional APC compartment by ~ 1000 -fold (Mai *et al.*, 2013; Yano *et al.*, 2006)) and its frequent contacts with recirculating lymphocytes provide significant opportunity to influence Ag-specific responses. Moreover, the unique and strategic anatomical positioning of BECs would allow them to exert qualitatively distinct and locally tuned regulation within the periphery. Below we summarize most well-established APC functions of BECs in both healthy and pathologic immunity. These highly varied, and in some cases opposing (e.g., activation vs. tolerance/anergy), functions reflect highly heterogeneous contexts in which they develop.

Reactivation of effector/memory T cells

Many studies have demonstrated *in vitro* that human umbilical vein BECs (HUVEC; a classically used *in vitro* BEC model), as well as dermal and lung microvascular BECs can activate proliferation and inflammatory cytokine secretion (e.g., IFN- γ , IL-2, IL-4, IL-10) in resting CD4 memory cells in a manner that is enhanced by co-stimulators such as ICOS-L and CD40 (Marelli-Berg *et al.*, 1996; Ma and Pober, 1998; Perez *et al.*, 1998; Sage *et al.*, 2012; Khayyamian *et al.*, 2002). Similarly, effector/memory CD4 lymphocytes can be directly activated by allogeneic endothelium both *in vitro* and *in vivo* in an MHC-II-dependent manner (Shiao *et al.*, 2005; Pober, 1999). Additionally, presence of MHC-I bearing cognate Ag on BECs promotes CD8 CTL activation and EC killing, though these responses are partially mitigated by concomitant BEC expression co-inhibitors (i.e., PD-L1, PD-L2) (Grabie *et al.*, 2007; Sage *et al.*, 2012; Rodig *et al.*, 2003; Dengler and Pober, 2000). Studies such as these suggest a general ability of BECs to promote Ag-dependent pro-inflammatory responses as lymphocytes home to tissues.

Maintenance/promotion of tolerance

The idea that BECs can provide a form of peripheral tolerance has been evidenced in diverse settings (Marelli-Berg and Lechler, 1999). For example, early *in vitro* work introduced the idea of transmigration anergy, whereby Ag encounter during diapedesis in the context of insufficient co-stimulation, led to a state of nonresponsiveness to a second APC/Ag encounter (Kawai *et al.*, 2000). This concept has been particularly well developed in settings of liver sinusoidal endothelial cell (LSEC) and LECs.

LSECs

The liver is known to provide an important tolerogenic environment (Thomson and Knolle, 2010; Crispe, 2009). Among the essential APCs in this organ (i.e., liver DCs, Kupffer cells, and LSECs), LSECs exhibit unique tolerogenic functions (Thomson and Knolle, 2010; Crispe, 2009). At steady-state circulating effector lymphocytes are able to make repeated transient (~10–20 min) direct contacts with LSEC *in vivo* without the need for diapedesis (Carambia *et al.*, 2013). LSEC have been shown to possess potent scavenger functions (that are comparatively more efficient than those of liver DCs) (von Oppen *et al.*, 2009; Schurich *et al.*, 2009; Sorensen *et al.*, 2012) and can effectively cross-present exogenous Ag to CD8 T cells to promote tolerance (Limmer *et al.*, 2000). LSEC also suppress pro-inflammatory Th1 and Th17 responses in an Ag-specific and IL-10- and PD-L1-dependent manner (Carambia *et al.*, 2013; Knolle *et al.*, 1999; Klugewitz *et al.*, 2002). Finally, LSEC exhibit superior efficacy (i.e., as compared to liver DCs and Kupffer cells) in promoting differentiation of CD4 Tregs that suppress inflammation and induce tolerance. This is accomplished through the unique composition of the LSEC glycocalyx (which includes the glycoprotein GARP) that uniquely enables cell surface capture and presentation of the critical Treg cytokine TGF- β (Carambia *et al.*, 2014).

LECs

LECs are also emerging as an important player in shaping immunity and tolerance (Tewalt *et al.*, 2012a; Card *et al.*,

2014). Lymphatic vessels and the contiguous subcapillary, cortical, and medullary sinuses of the SLOs provide a conduit for movement of lymphocytes. LECs of the lymph node sinuses constitutively express MHC-I and -II and under noninflamed conditions take up and cross-present peripheral tissue Ags to CD8 T cells in a lysosome- and TAP1-dependent manner (Hirose *et al.*, 2014). As a result of the absent co-stimulatory and high co-inhibitory (i.e., PD-L1) molecule expression on these LECs, such cross-presentation induces abortive proliferation and clonal deletion of self-reactive CD8 lymphocytes (Cohen *et al.*, 2010; Tewalt *et al.*, 2012b). Since lymphocytes must cross the cortical and/or medullary LECs in order to egress from the lymph node, these ECs are proposed to serve as anatomical checkpoint to enforce self-tolerance in lymphocytes attempting to exit the lymph node (Tewalt *et al.*, 2012a). While MHC-II on LECs is functional (as evidenced by the ability of peptide pulsed LECs to induce proliferation of CD4 cells) the overall roles of these APCs in class II immune responses remain to be determined (Tewalt *et al.*, 2012a; Card *et al.*, 2014).

Altered trafficking

A range of studies have demonstrated influences of EC Ag presentation on T cell trafficking behaviors. For instance, recognition of MHC-II/cognate Ag presented on EC was shown to cause a migratory stop signal in CD4 T cells that could prevent or transiently delay diapedesis across EC *in vitro* (Manes *et al.*, 2007; Sage *et al.*, 2012; Tay *et al.*, 2003). Other *in vitro* and *in vivo* studies support the intriguing hypothesis that Ag presented on the endothelium promotes the selective diapedesis of Ag-reactive CD4 and CD8 T cells. This seems in part to be mediated through an ability of TCR signaling events (i.e., activation of tyrosine kinase Zap-70) to cross talk with cell migration machinery (e.g., Rac-1, myosin-IIA) (Manes and Pober, 2008, 2013). In this way, Ag-specific effectors may more effectively home to the original tissue source Ag where pathogens have infected (Marelli-Berg *et al.*, 1999, 2004, 2007; Savinov *et al.*, 2003; Manes and Pober, 2008). It has been shown that the specific co-stimulatory/co-inhibitory molecules' expression patterns on the endothelium can strongly influence this process (David and Marelli-Berg, 2007). Additionally, recent studies demonstrate that recruitment of Treg to sites of inflammation is strongly favored by their ability to recognize self-Ags presented by endothelium (Fu *et al.*, 2014). As a result, the normally low numbers of Tregs that exist in the body can be optimally recruited to ensure sufficient numbers to balance out pro-inflammatory effector lymphocytes during resolution of inflammation (Fu *et al.*, 2014).

Roles for Endothelial Antigen Presentation in Pathology

Although roles in protective immunity are still emerging, strong connections of EC Ag presentation to immune pathology have been established. For example, endothelial expression of MHC-II molecules is significantly upregulated in a range of autoimmune/inflammatory diseases including multiple sclerosis, rheumatoid arthritis, diabetes, lupus, Crohn's disease, allograft rejection, dilated cardiomyopathy, myocarditis, and vasculitis (Turesson, 2004; Barkley *et al.*, 1989).

Additionally, alteration in the endothelial expression of critical co-stimulatory molecules and co-inhibitory molecules (e.g., CD40 and PD-L1) has been implicated in the pathogenesis of autoimmune diseases (Hollenbaugh *et al.*, 1995; Grabie *et al.*, 2007; Rodig *et al.*, 2003; Eppihimer *et al.*, 2002). Particularly, compelling functional evidence for a pathogenic role of EC Ag presentation exists in:

Allograft rejection

Perhaps the clearest evidence for functional roles of EC MHC is seen in the extensive *in vitro*, *in vivo* and clinical investigation of transplantation and allo-responses (Denton *et al.*, 2000; Pober, 1999; Taflin *et al.*, 2011; Rose, 1998). Effector/memory CD4 and CD8 lymphocytes are well-evidenced to be activated directly by allogeneic endothelium *in vitro* (Shiao *et al.*, 2005; Pober, 1999). Similarly, *in vivo* the endothelium of solid organ transplants (the first cell surfaces that host lymphocyte encounter) plays a pivotal MHC-dependent role in stimulating allo-responses and also can become a major target for CD8-mediated destruction. Moreover, in studies examining graft versus host disease, associated with stem cell transplantation, allo-reactive donor CD8 CTLs were demonstrated to be directly responsible for endothelial injury (Biedermann *et al.*, 2002).

Multiple sclerosis

Early studies using an animal model of MS (Experimental Autoimmune Encephalitis) demonstrated that MHC II expression on brain microvascular endothelium preceded the formation of T cell infiltrates, suggesting a role for EC Ag presentation in this process (Sobel *et al.*, 1984). Subsequent studies demonstrated that MHC-I/Ag presented on the luminal surface of the blood–brain barrier was responsible for Ag-specific trafficking of T cells to the CNS (Galea *et al.*, 2007). *In vitro* studies have also demonstrated that human brain ECs constitutively co-express of MHC-IMHC II, CD40, and ICOSL, take up fluorescently labeled Ags via macropinocytosis and promote Ag-dependent proliferation of CD4 and CD8 T cells (Wheway *et al.*, 2013).

Diabetes

In vitro studies have demonstrated that human ECs can process the diabetes type I islet autoantigen GAD65 and functionally present it on MHC-II molecules to promote selective transmigration of Ag-specific Th1 lymphocytes (Greening *et al.*, 2003). Similarly, using murine model of type-I diabetes, insulin-specific CD8 lymphocytes were demonstrated to home to the pancreas in a manner that was dependent on endothelial presentation *in vivo* (Savinov *et al.*, 2003).

Bacterial super-antigen

Bacterial super-antigens (SAGs) can functionally mimic ‘high affinity’ agonistic peptide Ag by concomitantly binding (and effectively ‘bridging’) cell surface MHC-II and TCR independently of the peptide binding sites (Redpath *et al.*, 1999; Proft and Fraser, 2003). SAGs are effective tools (model Ags) that are widely used to study T cell activation. More importantly, these are also pathogens in a wide range of diseases, including arthritis, diabetes, multiple sclerosis/EAE, sepsis, toxic shock, Kawasaki disease, and idiopathic dilated cardiomyopathy that accumulate (Renno and Acha-Orbea, 1996). During many infections,

significant levels of SAGs appear in the blood where they can readily be captured on EC MHC-II and presumably signal circulating T cells. Compelling evidence exists, in at least one setting (Kawasaki disease) (Leung *et al.*, 1995), that SAG presented specifically by endothelial MHC-II is important for pathogenesis.

Antigen Recognition and Responses during Lymphocyte–Endothelial Interactions

ISs with APC models and professional APCs

It has become clear that many of the keys to understanding protective and pathologic Ag-specific responses are in understanding the fundamental cell biology of the T cell–APC interaction (Dustin, 2005). This has been intensely investigated for activation of lymphocytes by professional APCs or artificial APC models. Such studies show that initially, Ag recognition delivers a calcium-dependent migratory stop signal that allows formation of a more sustained interaction with the APC (i.e., IS) in which micron-scale clusters of TCR mediate active signaling at the periphery of the contact (Dustin *et al.*, 1997). Studies have also identified several cytoskeletal modulators (Cdc42, WASp, WAVE2, Vav1, Arp2/3, HS1) that are critical for IS formation (Huang and Burkhardt, 2007; Billadeau *et al.*, 2007).

T Lymphocyte ILP: Unique Ag-recognition sensory organelles

Detailed investigation of the coordinated cellular, molecular and signaling dynamics of responses to endothelial APCs are only beginning to emerge. In one study lung and dermal microvascular BECs presenting MHC-II/cognate Ag were shown to induce proliferation and stimulate INF- γ production in resting CD4 effector/memory lymphocytes (Sage *et al.*, 2012). Detailed dynamic imaging studies showed that such responses were initiated by a rapid flux of intercellular calcium that is coupled to a migratory stop signal, which was initiated within tens of seconds of contacting BEC bearing MHC-II. This was followed by nuclear translocation of NFAT within minutes (Sage *et al.*, 2012). Calcium signaling persisted for about 30–60 min, after which T cells resumed lateral migration and then underwent diapedesis, still bearing nuclear NFAT. Closer characterization of the subcellular dynamics and architecture of the T cell–BEC IS showed that T cells initiated ILP probing that enforced extremely close contacts with EC that preceded, and were required for, Ag-dependent calcium responses (Figure 6). The same was found for CD8 CTL calcium signaling and killing responses to EC presentation of MHC-I/cognate Ag (Sage *et al.*, 2012). Thus, the roles discussed of above for ILP in promoting efficient ‘informational scanning’ for EC surface chemokines (Shulman *et al.*, 2012) is also relevant for detection of MHC/Ag.

The critical role for ILP in Ag recognition is evident when we consider the topological features of the requisite cell–cell interaction. The surface of all cells are modified by a gel-like polysaccharide coating, termed the glycocalyx, that is made up of diverse proteoglycans and glycoproteins (Reitsma *et al.*, 2007; Weinbaum *et al.*, 2007). On a typical cell the glycocalyx is at least 45 nm thick, but may be substantially thicker (up to ~500 nm) on others, such as the endothelium (Reitsma *et al.*,

Figure 6 Model for ILPs function in Ag recognition and response schematic depicts top, down and side views of a memory/effector T cell (blue) interacting with an endothelium (pink) presenting cognate Ag. Lymphocytes initiate lateral migration (Step 1) and begin to dynamically drive ILPs against the opposing cell (Step 2, inset 2a). Close interactions between T and APC/target cells, which are partially opposed by the cell glycocalyx (inset 2b), form at ILP tips (inset 2c). Thus TCR/MHC interactions may be facilitated in these zones. Initial calcium released upon Ag recognition (green overlay/arrows; Step 3) seems to be coupled to stabilization/accumulation of ILP arrays ('podo-synapses'; Step 4), help sustain/enhance signaling (Step 5). The peripheral arrays of ILP seen in this setting as highly analogous to podosome belts that serve as a type cell–cell sealing apparatus for compartmentalized delivery of extracellular material, which in this case may include cytokine or cytotoxic agents released by the T cells.

2007; Weinbaum *et al.*, 2007). The glycocalyx serves several important functions, such as protection from proteases and stabilizing the orientation of adhesion and signaling receptors (Rudd *et al.*, 2001). At the same time the glycocalyx also provides a formidable energy barrier to close membrane–membrane encounter between cells, such that relatively small cell surface adhesion and signaling molecules (e.g., TCR and MHC, each ~7 nm tall (Rudolph *et al.*, 2006)) are effectively shielded (Bell, 1978; Bell *et al.*, 1984; Springer, 1990; Reitsma *et al.*, 2007; Weinbaum *et al.*, 2007; Figure 6). In this way, the glycocalyx negatively modulates immune cell adhesion and immune recognition (Gubbels *et al.*, 2010; Komatsu *et al.*, 1999; Tsuboi and Fukuda, 2001; Tsuboi and Fukuda, 1998; van de Wiel-van Kemenade *et al.*, 1993; Sabri *et al.*, 2000; Manjunath *et al.*, 1995; Stockton *et al.*, 1998; Onami *et al.*, 2002; McFarland *et al.*, 1995). Forces provided by ILPs appear to provide sufficient energy to overcome this barrier, driving close membrane–membrane apposition (Figure 6) and thereby promoting molecular interactions that might otherwise be inefficient or impossible.

Though the functional contribution of ILP have only recently been elucidated, it was previously established that the leading edge lamellipodia of migrating lymphocytes possess heightened Ag recognition capabilities (Valitutti *et al.*, 1995;

Negulescu *et al.*, 1996; Wei *et al.*, 1999). It would now appear that the ILP, which from preferentially within lamellipodia (Carman *et al.*, 2007; Sage *et al.*, 2012; Martinelli *et al.*, 2014), represent the direct 'actuators' of the special immune surveillance capabilities found at the T cell leading edge.

Stabilized ILP arrays function in signal amplification

Following initial Ag recognition, the resulting intracellular calcium flux concomitantly drives a migratory stop signal and stabilization of ILPs. This causes ILPs to accumulate preferentially around the periphery of the T cell–EC interface in dense arrays forming a unique IS topology termed a 'podo-synapse' (Sage *et al.*, 2012; Figure 6). The individual Ag stabilized lymphocyte ILPs are enriched in actin, TCR and molecules suggestive of active signaling (e.g., PKC- θ , phospho-tyrosine and HS1), whereas the cognate endothelial contact sites (i.e., podo-prints) are enriched in MHC (Figure 7). Thus, ILPs may function to promote sustained TCR signaling by providing specialized sub-micron-scale cylindrical volumes to increase signaling efficiency in analogy to well-developed concepts for 'signalosomes' (Burbach *et al.*, 2007; Perez-Moreno *et al.*, 2003; Harwood and Batista, 2008; Vicente-Manzanares and Sanchez-Madrid, 2004; Miranti and Brugge, 2002). This feature is generally not unlike TCR signaling micro-clusters defined using

Figure 7 Ultrastructure and fluorescence imaging of the podosynapse images show CD4 effector/memory lymphocytes interacting with microvascular endothelial cells presenting MHC-II/cognate Ag. Upper panels show ultrastructural imaging of a lymphocyte (blue) extending multiple ILP into the endothelium, generating zones of close cell–cell interaction, and EC deformation (i.e., creating multiple EC ‘podo-prints’). Lower panels depict light microscopy imaging of T cells (by differential interference contrast (DIC) and fluorescence imaging). T cell ILP is enriched in actin and TCR (Red). Podo-prints in endothelium are evidenced as rings of plasma membrane (mem-YFP) and are enriched in MHC-II (green).

planar lipid bilayer APC model substrates (Dustin *et al.*, 2006; Saito and Yokosuka, 2006; Brossard *et al.*, 2005; Dustin, 2009; Seminario and Bunnell, 2008; Gomez *et al.*, 2006; Yokosuka *et al.*, 2005; Bunnell *et al.*, 2002) and ‘multi-focal’ ISs noted to form on DC (Dustin *et al.*, 2006; Saito and Yokosuka, 2006; Brossard *et al.*, 2005).

At a higher level of organization, the ILP arrays may provide additional functions in promoting T cell–EC information exchange. Specifically, the podo-synapse exhibits striking topological similarity to osteoclast ‘podosome-belts’ (Luxenburg *et al.*, 2007; Destaing *et al.*, 2008; Figure 6), structures that form sealing zones for directed secretion of bone degrading enzymes (Saltel *et al.*, 2004). Thus, an additional function of the podo-synapse may be similarly to direct secretion of cytokines (or cytotoxic agents) toward the target cell, while limiting bystander effects.

Lessons learned from BEC-APC as unique planar APC

The preceding discussion highlights ILP functions that could be envisioned as being broadly relevant ones. Whereas

commonly used APC models (planar lipid bilayer or coated glass/plastic model APCs substrates) provide ideal features (i.e., a planar surface oriented parallel to the optimal x-y imaging plane) for visualizing micron-scale topological dynamics, their inherently rigid nature would most likely frustrate and/or mask ILP extension in the z-plane. Alternatively, imaging of most physiologic and deformable APCs/targets is hindered by orientation issues that profoundly limit resolution (Oddos *et al.*, 2008; Balagopalan *et al.*, 2011; Cebecauer *et al.*, 2010). As an experimental model, BEC combine the strengths (i.e., near planarity and orientation) of model substrates and cellular APCs (deformability and active responses) forming a ‘planar cellular APC’ surface that is optimized for detection of ILPs, but not necessarily the only setting for their formation. Cross-sectional fluorescence and EM images of ISs formed with a range of (non-endothelial) APCs and targets show topologies consistent with presence ILPs (Bunnell *et al.*, 2006; Yokosuka *et al.*, 2005; Wetzel *et al.*, 2002; Butler *et al.*, 2008; Barcia *et al.*, 2008a,b, 2009; Davis, 2009; Sage *et al.*, 2012). Thus, ILP may

have broad function in Ag recognition and responses that are uniquely revealed the setting of EC Ag presentation, rather being a unique feature of this setting.

Summary

The endothelium represents a critical anatomical partition between the tissues and the blood/lymph system and also play essential proactive sentinel roles that regulate immunity. In particular, BECs and LECs act as coordinators of immune cell trafficking during maturation, surveillance and responses. Additionally, BECs and LECs co-express MHC-I, MHC-II and a wide array of co-stimulatory molecules and exhibit ‘semi-professional’ APC functions that can communicate Ag-specific information to effector/memory T cells in the periphery. Although these functions, by definition, will be secondary to those of professional APCs, the enormous scale and strategic anatomical positioning of the endothelial APC compartment suggest it may have important and unique functions in adaptive immunity, as well as immune pathologies. The ability of lymphocyte-endothelial interactions to so effectively orchestrate information exchange, trafficking events and Ag-specific responses is coupled with the mutual ability of these cells to engage in extremely intimate and dynamically coordinated interactions. Active embrace of T cells by endothelial cup-like structures promotes enhanced adhesion and guidance for diapedesis, while EC ventral lamellipodia restore barrier function following extravasation events. T cell ILPs have been uncovered as a critical sensory organelle that allows T cells to effectively survey both the biomechanical and biochemical properties of the endothelium (and likely other cells). In this way, ILP are both critical for T cell migratory pathfinding across the endothelial barrier (i.e., ‘tender-taxis’) and for detection of MHC-Ag on the BEC surface. With respect to the latter, stabilized arrays of ILPs (‘podo-synapses’) provides a unique IS architecture that functionally contributes to immune signaling at this interface in several ways. The preceding suggests that more clearly defining the diverse context-dependent roles of EC in Ag-specific immunity and the underlying cellular/molecular regulation represents areas of significant biomedical significance.

Introduction

Activation of T cells of the $\alpha\beta$ lineage depends on specific binding of the T cell antigen receptor (TCR) to its ligand, a cognate peptide bound to a major histocompatibility complex molecule (pMHC), at the cell surface of antigen presenting cells (APCs). Their TCR is composed of a clonotypic, antigen specific TCR $\alpha\beta$ heterodimer, and the invariant and signal transducing CD3 $\gamma\epsilon$, CD3 $\delta\epsilon$, and CD3 $\zeta\zeta$ dimers (Kuhns and Badgandi, 2012; Figure 1). The recognition and signaling components of the TCR are therefore located in different protein subunits and signal transduction via the TCR is therefore strictly dependent on communication between these components. Binding of TCR $\alpha\beta$ to its pMHC ligand leads to the phosphorylation of the intracellular immunoreceptor tyrosine-based activation motifs (ITAMs) of the CD3 $\gamma\epsilon$, CD3 $\delta\epsilon$, and CD3 $\zeta\zeta$ dimers by the CD4 or CD8 co-receptor-associated src-family kinase Lck, allowing recruitment of the ZAP70 protein tyrosine kinase (PTK) via its tandem SH2 domains, which in turn phosphorylates a number of downstream signaling components (Smith-Garvin *et al.*, 2009). However, not all TCR signaling is mediated by ITAMs: other sequences within the intracellular domains, such as the basic-rich stretches (BRS) of CD3 ϵ and CD3 ζ and the proline-rich sequence (PRS) of CD3 ϵ have more recently been shown to be critical for full functionality of the TCR (Boroto *et al.*, 2013, 2014; Brodeur *et al.*, 2009; Deford-Watts *et al.*, 2009; Mingueneau *et al.*, 2008; Bettini *et al.*, 2014).

A difficulty to understand how the TCR transmits outside-in signals emerges from the unavailability of a high-resolution structure of the entire complex. In lack of this essential information, partial structures of isolated dimers (ectodomains of TCR $\alpha\beta$, ectodomains of CD3 $\gamma\epsilon$, ectodomains of CD3 $\delta\epsilon$, transmembrane domain of CD3 $\zeta\zeta$, and cytoplasmic tail of CD3 ϵ) have been characterized. Most crystal structures of the TCR $\alpha\beta$ extracellular domain in free form or bound to its pMHC ligand show little or no differences between these structures (Rudolph *et al.*, 2006). However, the crystal structure of the $\alpha\beta$ LC13 TCR showed a shift in the AB loop of the α domain induced by pMHC ligand binding (Kjer-Nielsen *et al.*, 2003). This shift was later confirmed by fluorescence spectroscopy methods (Beddoe *et al.*, 2009). To what extent is this AB loop shift a peculiarity of this TCR, or a generalized phenomenon is not uncovered due to poor resolution of the α domain, and to what level such shift intervenes in the transmission of TCR-to-CD3 conformational changes remains to be clarified. Outside-in transmission of the occurrence of a TCR $\alpha\beta$ -pMHC interaction may therefore rely on conformational changes that reorientate TCR $\alpha\beta$ in relation to the CD3 components, on TCR clustering provoked by pMHC ligand-induced crosslinking or on the recruitment or exclusion of other molecules. All of these mechanisms have to account for the unusual combination of properties of TCR-mediated activation of T cells: a very low affinity of the TCR-pMHC

interaction (Alam *et al.*, 1999), very high sensitivity and specificity for antigen (Huang *et al.*, 2013; Irvine *et al.*, 2002; Reay *et al.*, 2000; Sykulev *et al.*, 1996), and ability to induce different signaling outputs and cell fates in response to different pMHC ligands both during T cell differentiation in the thymus and activation in the periphery (Daniels *et al.*, 2006; Sloan-Lancaster *et al.*, 1994). In this article we will focus on experimental evidence that explain the molecular mechanisms

Figure 1 Schematic representation of the TCR complex. Domains discussed in this article are indicated. Semicircles represent the Ig superfamily immunoglobulin-like extracellular domains of the TCR and CD3 chains. Intra- and interchain disulfide bonds are represented by thin dashed lines. Colors of the chains and domains are maintained in all figures, although for clarity sake simplified representations omitting certain domains and chains are used.

that transmit the occurrence and quality of the extracellular pMHC-TCR $\alpha\beta$ interaction to the intracellular domains of the CD3 and CD3 $\zeta\zeta$ dimers.

Time of Interaction and Recruitment of Modulators

One of the basic tenets of T cell activation has been that the quality of the TCR-pMHC ligand interaction determines the quality of the T cell response. Measurements of kinetic parameters for the TCR-pMHC interaction in solution by surface plasmon resonance showed that the degree of activation of T cells by related pMHC ligands correlated to a reasonable extent with the off-rate of the interaction between their TCRs with these pMHC ligands (Alam *et al.*, 1999; Rosette *et al.*, 2001). These findings lead to the formulation of kinetic proofreading (McKeithan, 1995) and kinetic discrimination (Rabinowitz *et al.*, 1996) models that postulate that the time of the TCR-pMHC interaction (dwell time, dependent on the off-rate of the interaction) determines the time-dependent extent of TCR activation (e.g., phosphorylation of ITAMs, recruitment of downstream effectors such as ZAP70), which in turn determines the degree of response. These models did, however, not provide a mechanistic explanation of how the occurrence and duration of TCR-pMHC binding was transmitted to the downstream effectors.

A mechanistic insight has been provided by Palmer and colleagues who studied a correlation between kinetic parameters of TCR-pMHC interaction and positive and negative selections during T cell maturation in the thymus (Palmer and Naeher, 2009). The fate of thymocytes is determined by the interaction of their TCR with self-pMHC complexes expressed by thymic stroma: thymocytes expressing TCRs with low affinity for self-pMHC receive signals that activate a survival and differentiation program (positive selection) leading to maturation into MHC-restricted, functional T cells, whereas thymocytes expressing TCRs with high affinity for self-pMHC activate signaling pathways that lead to apoptosis (negative selection) and thus prevent the presence of strongly self-reactive T cells in the repertoire (Starr *et al.*, 2003). Palmer and colleagues found for three different TCRs that a very discrete threshold separates the longer dwell times of pMHC ligands that cause negative selection from the shorter dwell times of positively selecting pMHC ligands (Naeher *et al.*, 2007). This threshold dwell time (around 4 s) seems to be a constant, suggesting a general time-determined underlying molecular mechanism. This mechanism has been proposed to rely on CD4 or CD8 co-receptor recruitment to the TCR which would be more efficiently recruited upon ligation by high- than by low-affinity pMHC (Mallaun *et al.*, 2008). This differential recruitment of the co-receptor would result in differential recruitment of co-receptor-associated Lck (Rudd *et al.*, 1988; Veillette *et al.*, 1988) to the intracellular domains of the TCR and therefore more extensive phosphorylation of the ITAMs. The extent of ITAM phosphorylation would then in turn enable more or less efficient recruitment of downstream effectors and therefore intensity of signaling. Interestingly, co-receptor recruitment to the TCR is not only mediated by co-receptor binding to the constant domains of pMHC (Doyle and Strominger, 1987; Norment *et al.*, 1988) but also depends on

the extracellular, membrane-proximal connecting peptide motif (α CPM) domain of the TCR α chain, since T hybridomas lacking the α CPM show reduced pMHC-dependent co-receptor recruitment and reduced ITAM phosphorylation (Mallaun *et al.*, 2008), and thymocytes without this domain cannot respond to positively selecting pMHC ligands, as evidenced by impaired ERK phosphorylation, and DP arrest (Werlen *et al.*, 2000). These findings have led to the proposal that close association of the co-receptor (and therefore Lck) with the TCR is a step-wise, time-dependent 'zipper' process (Figure 2) in which the available time, depending on the duration (i.e., affinity) of the TCR-pMHC interaction, determines the degree of co-receptor-mediated Lck recruitment. This would in turn determine the extent of ITAM phosphorylation, which has been shown to regulate the biological response (Holst *et al.*, 2008; Kersh *et al.*, 1998).

The correlation between dwell time and dissociation constant (k_{off}) on one hand and biological activity on the other is good when kinetic data is calculated in tridimensional (3D) settings, such as via surface plasmon resonance in which at least one of the components (TCR or pMHC) is in solution. However, this correlation is lost when two different approaches are used that measure the affinity and kinetics of TCR-pMHC interaction with both components bound to biological membranes and restricted to diffusion in two dimensions (2D). These two systems, that have the capacity of single receptor-ligand pair resolution, have shown that the 2D affinity and 2D on-rate of this interaction corresponds very well to the stimulatory capacity of these pMHC ligands (Huang *et al.*, 2010; Huppa *et al.*, 2010). Surprisingly, the average dwell time for strongly activating ligands was shorter than for weakly activating ligands (due to very fast off-rates) (Huang *et al.*, 2010). This would contradict the above-described time of interaction models and might hint at models where rapid pMHC sampling by the TCR and the degree of accumulation of a transient secondary messenger were the underlying determinants of T cell activation.

Exclusion of Negative Regulators

In a classic review on adhesion receptors of the immune system, Timothy Springer pointed out that the extracellular domains of the various receptor-ligand pairs that form in the contact area between the T cell and APC showed important size differences and that this might lead to regions within the contact area with different intermembrane spaces (Springer, 1990). He suggested that as a consequence proteins with large extracellular domains, such as the protein tyrosine phosphatase CD45, might be separated from or reoriented with respect to smaller receptor-ligand pairs such as TCR-pMHC and that this might influence signaling. The relevance of protein tyrosine phosphatase activity in regulating TCR signaling was underscored by experiments that showed that treatment of T cells with protein tyrosine phosphatase inhibitors such as pervanadate gave rise to a series of proximal and distal T cell activation events that closely resemble those induced by TCR-dependent stimuli (Secrist *et al.*, 1993). Thus the resting state of the TCR was actively maintained by tyrosine phosphatases and part of TCR-mediated signal transduction might depend

Figure 2 Zipper model of TCR triggering. Upon engagement with a cognate pMHC (peptide represented by magenta-colored circle) the co-receptor (represented in orange; CD4 for MHC class II restricted T cells, CD8 for MHC class I-restricted T cells) will bind to the MHC molecule (represented in blue). This will bring Lck, associated with the intracellular domain of the co-receptor, closer to the ITAM domains of the CD3 chains causing partial phosphorylation (red circled P). If the dwell time of the TCR–cognate pMHC interaction is sufficiently long, the co-receptor will also be able to bind the α CPM domain of TCR α (indicated in red) allowing for a closer proximity of Lck to the ITAM domains of the CD3 chains and hence more extensive ITAM phosphorylation.

on inhibition of the TCR-proximal phosphatase activities. This control of tyrosine kinases could be exerted by membrane-bound and/or cytosolic phosphatases, but the focus was put on membrane-bound phosphatases such as CD45, one of the most abundant membrane-associated phosphatases on T cells with both inhibitory and stimulatory effects on T cell activation (Rhee and Veillette, 2012), as it was shown to be absent from actively signaling TCRs of T cells stimulated via supported lipid bilayers (SLB) containing cognate pMHC complexes and ICAM-1 (Varma *et al.*, 2006) or, less physiologically, stimulated on coverslips coated with immobilized anti-CD3 antibodies (Bunnell *et al.*, 2002). These observations have led to the definition of the kinetic segregation model (Davis and van der Merwe, 2006), which proposes that, due to their large extracellular domain, CD45 and the CD148 phosphatase are excluded from the relatively narrow contact zone established between the T cell and the APC by the interaction between the TCR and pMHC and other receptor–ligand pairs that all have much shorter extracellular domains (Figure 3). Evidence in favor of this model is the observation that transfection of cell lines with recombinant CD45 molecules with shorter extracellular domains inhibits early (ZAP70 phosphorylation) and late (IL-2 production) T cell activation steps (Cordoba *et al.*, 2013). Vice versa, APCs expressing pMHC with enlarged extracellular domains are less stimulatory than APCs expressing MHC of ‘normal’ length (Choudhuri *et al.*, 2005, 2009). These observations suggest that the size of the extracellular domain of the CD45 and CD148 phosphatases relative to the dimensions of the extracellular pMHC and TCR domains determines their degree of exclusion and therefore, the degree of tyrosine phosphorylation. However, it has been

Figure 3 Kinetic segregation model. Recognition of the cognate pMHC on the APC generates a TCR-dependent force (represented by brown dashed arrows) that brings the opposing membranes of the T cell and APC in closer contact. This forces the segregation of the CD45 phosphatase (dark green) from the contact area, due to its long and rigid extracellular domain (top). Concurrent recruitment of Lck results in a shift in the balance of kinase and phosphatase activity and leads to more extensive ITAM phosphorylation (bottom).

shown in a reconstituted T cell/B cell interaction model that a CD45 recombinant with a short CD86-derived extracellular domain as well as unbound CD58 are significantly excluded from the contact area (James and Vale, 2012), indicating that size alone may not be the only determinant for exclusion from the contact area. Regardless of the relevance of ectodomain size-based phosphatase exclusion on TCR signaling, it is still pending to clarify if phosphatase exclusion is a mechanism that 'initiates' TCR signaling or just a mechanism for sustainment and amplification of the initial signal.

Changes in Conformation and Accessibility of Intracellular Domains

Engagement of the TCR ectodomains with antigen-loaded APCs, soluble pMHCs and antibodies against the extracellular domains of TCR $\alpha\beta$ or CD3 $\gamma\epsilon$ and CD3 $\delta\epsilon$ leads to exposure of the intracellular, membrane-proximal PRS of the CD3 ϵ chain, permitting the recruitment of the SH2- and SH3-domain containing adaptor protein Nck to the PRS (Gil *et al.*, 2002; Minguet *et al.*, 2007; Risueno *et al.*, 2005; Figure 4(a)). Ligand-induced binding of CD3 ϵ to Nck is independent of tyrosine phosphorylation, is induced at 0 °C, and can be triggered on cell-free purified TCR complex. This represents all hallmarks of a conformational change in the TCR complex. Transmission of the extracellular engagement to the CD3 ϵ PRS critically depends on the extracellular, membrane-proximal stalk region of CD3 ϵ . Molecular dynamics analysis of the extracellular domain of CD3 $\delta\epsilon$ dimer in presence and absence of a conformational change-inducing antibody showed that antibody binding made the stalk region more rigid (Martinez-Martin *et al.*, 2009). The molecular dynamics analysis also identified amino acid residues in the stalk, in close proximity to or part of an evolutionary conserved CXXC motif (Wang *et al.*, 2009), that appeared critical for the formation of the rigid stalk. Single mutations of these residues in full length CD3 ϵ chains impaired the antibody-mediated induction of the conformational change when these mutated CD3 ϵ chains were expressed in a murine T cell hybridoma (Martinez-Martin *et al.*, 2009). This coincided with reduced phosphorylation of the CD3 ζ chain and ERK and a diminished effector response upon activation with APCs loaded with graded amounts of the antigenic peptide. This means that transmission of the occurrence of the physiologically relevant interaction between cognate pMHC and TCR $\alpha\beta$ to the downstream signaling pathways is quantitatively dependent on the stalk region of the CD3 dimers. The mutated CD3 ϵ chains exerted a strong dominant negative effect as they were co-expressed with the wild type CD3 ϵ chains of the murine T hybridoma. This can only be explained by assuming the need of extensive collaboration between individual TCR complexes during TCR triggering. In an alternative study it was shown that mice, expressing CD3 ϵ chains with both of the cysteines of the CXXC motif mutated to serines, had defects in TCR signaling dependent thymocyte differentiation steps and reduced mature T cell responses (Wang *et al.*, 2009), underscoring the importance of the stalk domain in proper TCR triggering. It was not reported whether this mutated CD3 ϵ chain was able to undergo the conformational change. More recently, it has been shown that the CXXC

motif in the stalk of CD3 ϵ is oxidized, forming a small intra-chain disulfide loop (Brazin *et al.*, 2014). A CXXC motif is also present in the stalk regions of CD3 γ and CD3 δ . Interestingly, Cys-to-Ser mutation of the CXXC motif in CD3 δ leads to changes in NMR spectra of amino acids of the transmembrane domain and even cytoplasmic amino acids as far down as the ITAM motif (Brazin *et al.*, 2014). These results suggest that the four CXXC motifs present in the CD3 $\gamma\epsilon$ and CD3 $\delta\epsilon$ dimers intervene in the outside-in transmission of conformational changes.

Efficient induction of the conformational change and downstream signaling events by soluble ligands depends on multivalent ligands and close spacing of the engaged TCRs (Minguet *et al.*, 2007). Monovalent antibody (Fab) fragments specific for CD3 can induce the conformational change to a certain extent, but are unable to induce downstream signaling events. Upon combination of these Fab fragments with artificial ligands that bring TCRs in close proximity but by themselves cannot induce the conformational change or downstream signaling, an increased level of conformational change and downstream signaling is detected. These findings, together with the fact that all natural TCR $\alpha\beta$ heterodimers bind pMHC with an approximately 30° angle (Rudolph *et al.*, 2006), have led to a TCR triggering model (the permissive geometry model; Figure 4(b)) in which binding of multivalent pMHC to a clustered TCR provides both anchoring points and force that allow the engaged TCR $\alpha\beta$'s to reposition relative to each other, which in turn generates force on the associated CD3 dimers and induces the conformational change (Minguet *et al.*, 2007). Finally, maintenance of the conformational change is dependent on continued ligand binding (Minguet *et al.*, 2007), providing a potential role for ligand affinity in regulating the conformational change-dependent signaling pathways. It was found in two mouse models of thymic differentiation that only high affinity, negative selection inducing interactions gave rise to a conformational change, providing a potential mechanism via which TCRs in the thymus can activate different signaling pathways during positive and negative selection (Risueno *et al.*, 2006). Studies on another model of thymic selection indicated that this discriminating capacity is developmentally regulated, as in preselection thymocytes both low- and high-affinity pMHC ligands induced the conformational change, whereas in positively selected thymocytes and mature T cells only high-affinity ligands induced the conformational change (Gil *et al.*, 2005, 2008).

Regulation of the accessibility of the ITAM domains of the CD3 chains for Lck and ZAP70 may represent another mechanism of TCR signaling that could be part or not of the outside-in conformational change described above. Interestingly, it has been described that the activity of Lck does not change upon TCR triggering, thus leaving regulation of ITAM phosphorylation to a matter of Lck localization or, alternatively, to a regulation of exposure of the ITAM sequences to the kinase (Nika *et al.*, 2010). *In vitro* studies showed that recombinant proteins representing the intracellular domains of CD3 ϵ and CD3 ζ specifically associate with unilamellar vesicles composed of acidic phospholipids (Aivazian and Stern, 2000; Sigalov *et al.*, 2006; Figure 4(c)). These studies also showed that ITAM-phosphorylated versions of these proteins lost their lipid binding capacity and vice versa: once associated to the lipid

Figure 4 Conformation and accessibility changes and force as mediators of TCR triggering. (a) Interaction of the TCR with cognate pMHC leads to stiffening of the extracellular stalk domain and a conformational change in the intracellular tail of CD3 ϵ leading to exposure of the PRS. This allows for recruitment of the adaptor protein Nck. (b) The permissive geometry model proposes that binding of minimally bivalent pMHC is necessary to force a rearrangement of the TCR and CD3 chains that will result in the conformational change (top view of TCR-CD3 and pMHC). (c) The intracellular tails of CD3 ϵ chain and ζ are embedded in the inner leaflet of the plasma membrane of resting T cells in a phospholipid and BRS-dependent fashion, impeding access of Lck to the ITAMs (top). TCR triggering leads to release from the membrane, involving a TCR triggering-dependent influx of Ca^{2+} ions and competition between these Ca^{2+} ions and the BRS for the negatively charged phospholipids (bottom). (d) Interaction of the TCR with cognate pMHC provides an anchoring point to the TCR which allows it to exert force on the other components of the complex, either due to T cell movement during scanning of the APC or due to actin-dependent transport of TCR microclusters toward the immunological synapse.

vesicles, they became refractory to src kinase-mediated ITAM phosphorylation. NMR analysis indicated that the non-phosphorylated tyrosine residues of these recombinant proteins were deeply buried in the lipid bilayer, suggesting a mechanism to regulate their accessibility to PTKs and hence T cell activation (Xu *et al.*, 2008). Additional studies showed that binding of the CD3 ϵ and ζ intracellular domains to the unilamellar vesicles depended on clustered basic residues, the BRS, in these intracellular domains (DeFord-Watts *et al.*, 2009, 2011; Xu *et al.*, 2008). Recombinant proteins containing the CD3 ϵ or ζ intracellular domains with a C-terminally associated fluorescent probe were generated to study by Förster resonance energy transfer (FRET) the relevance and mechanisms of the membrane association and dissociation in T cell lines (Gagnon *et al.*, 2012; Zhang *et al.*, 2011). The recombinant CD3 ζ protein associated with the endogenous TCR components and its intracellular domain was associated with the plasma membrane in a BRS-dependent manner under resting conditions (Zhang *et al.*, 2011). TCR triggering by anti-CD3-coated beads caused dissociation from the membrane in the contact area between the bead and the T cell. This dissociation was dependent on phosphorylation of the ITAM sequences, as constructs with mutations of the Tyr residues to Phe remained associated to the membrane upon stimulation. In contrast, the study of the CD3 ϵ recombinant, for which it was not shown that it incorporated into the TCR complex and which had both Tyr residues of the ITAM replaced by Phe, showed that this chain was released from the plasma membrane upon pMHC-mediated TCR triggering independent from phosphorylation (Gagnon *et al.*, 2012). It is not clear whether this apparent contradiction reflects possible chain-specific differences under physiological conditions or is due to the properties of the recombinant proteins used in these studies. Finally, intracellular Ca²⁺ ions were shown to release the intracellular domains of recombinant CD3 ϵ from the plasma membrane by competing with the BRS for binding to the phosphate groups of the anionic phospholipids in the inner leaflet of the plasma membrane (Shi *et al.*, 2013), suggesting a positive feedback role of the TCR triggering-dependent Ca²⁺ influx in T cell activation.

TCRs as Mechanoreceptors

Application of force on TCRs changes the T cell's response to antigen. A non-stimulatory, bead-bound CD3-specific antibody could be rendered stimulatory, as measured by induction of Ca²⁺ influx, by applying force on the bead via optical tweezers (Kim *et al.*, 2009). In this setting, force was effective if the bead was moved parallel to the cell surface of the T cell, not when moved perpendicular to the cell surface, leading to the suggestion that the TCR was a directionally dependent mechanosensor. This tangentially applied force on the CD3 dimer was speculated to mimic the sideward push applied by the adjacent TCR $\alpha\beta$ when, due to its binding to its pMHC ligand on the APC, it was either bent because of the pull generated by the scanning movement of the T cell over the APC (Friedl and Brouck, 2002), or because of the actin-dependent movement of TCR microclusters (Yokosuka and Saito, 2010; Figure 4(d)). Another study showed that a weakly

stimulating artificial TCR ligand, an anti-CD3 single chain fragment coupled to the extracellular domain of CD43 expressed at the cell surface of a fibroblast, became a much more potent stimulator in combination with a tangential shear force applied to the ligand-bound T cell, or when the ligand-bound T cell was gently pulled away from the fibroblast (Li *et al.*, 2010). This would suggest that the direction of the force was less restricted than proposed by Kim and coworkers. However, these were in both cases cell-based experiments with numerous TCR–ligand interactions involved at the same time. Given that the T cell–APC interface is not necessarily a perfect plane (Roybal *et al.*, 2013), it is not straightforward to extrapolate the direction of the force applied to the whole cell to the direction of the force on individual TCR–ligand pairs.

2D affinity measurements with a biological force probe (BFP) under zero-force conditions had, as previously mentioned, shown that the biological potency of a range of pMHC ligand correlated directly with the affinity of the TCR–pMHC interaction but correlated inversely with the dwell time (Huang *et al.*, 2010). Repetition of these interaction studies under increasing pulling force conditions (applied via the BFP) showed that weak ligands formed 'slip bonds': dwell time decreased when the amount of force applied to the interaction was increased. In contrast, strong ligands formed 'catch bonds' with the TCR: dwell time reached an optimum when increased force was applied (Liu *et al.*, 2014). Furthermore, this maximal dwell time correlated with a maximal T cell response (measured as a Ca²⁺ influx). Interestingly, applying pulling force conditions resulted in a perfect correlation between dwell time and biological potency of a panel of pMHC ligands. Applying the same range of force via a TCR $\alpha\beta$ -specific antibody (which formed slip bonds but, due to its high affinity, resulted under all force conditions in dwell times longer than those obtained with the strongest pMHC) showed that maximal induction of response (Ca²⁺ flux) was obtained under the same force conditions observed for the strong pMHC. This coincidence suggests that both pMHC and the anti-TCR $\alpha\beta$ antibody act on the same force-requiring process in TCR triggering. The molecular basis of the pMHC–TCR $\alpha\beta$ catch bond formation (a functional description) is not known, but might be revealing with regard to the understanding of the mechanism of TCR triggering. Bearing all this data in mind, one has to consider that pulling or tangential forces could just be a mechanism to produce piston-like or rotational movements in the TCR and thereby provoke conformational changes.

In the above-mentioned experiments the role of force in TCR triggering was studied by applying an artificial force to the TCR–ligand pair. In support of the physiological relevance of force in TCR triggering, it has been shown that T cells can also generate force themselves upon TCR engagement. Using an alternative BFP setup that permits measurement of the force generated by the T cell, Husson *et al.* (2011) showed that T cells first apply an actin-dependent pushing force on an anti-CD3-coated bead, followed by a pulling force that eventually leads to engulfment of the bead. This pushing and pulling action is TCR-specific, as engagement of LFA-1 via an anti-LFA-1-coated bead did not lead to pushing and to marginal pulling. Pushing tended to start before detection of a Ca²⁺ influx, suggesting that it was a cause of TCR triggering although it does not exclude that it was a consequence.

Clustering

Whereas it has long been recognized that TCRs form microclusters upon antigen engagement (Krummel *et al.*, 2000; Campi *et al.*, 2005; Yokosuka *et al.*, 2005) it has only more recently been established by a variety of techniques that in the absence of ligands TCRs at the cell surface are present as a combination of preexisting oligomers with a variable size of up to 25 TCR complexes per cluster (Kumar *et al.*, 2011; Lillemeier *et al.*, 2010; Schamel *et al.*, 2005; Sherman *et al.*, 2011). These preformed TCR nanoclusters, whose existence is dependent on the presence of cholesterol in the plasma membrane, have been shown to enhance the sensitivity of the T cell for antigen (Kumar *et al.*, 2011; Schamel *et al.*, 2005). It has been proposed that this occurs via mechanisms implying cooperative ligand binding or signal transduction spreading (Figure 5; Alarcon *et al.*, 2006; Castro *et al.*, 2014; Martinez-Martin *et al.*, 2009). Direct experimental evidence for the molecular mechanisms that underlie this enhancement of sensitivity has not yet been reported. However, the 2D affinities of TCR–pMHC interactions are reduced when the interacting T cells are pretreated with cholesterol-depleting agents (Huang *et al.*, 2010; Huppa *et al.*, 2010), suggesting that cooperative binding of a cluster of pMHC ligands to a TCR nanocluster could occur.

Quantity and Valency of Cognate pMHC Ligands

Early studies on the number of pMHC complexes needed on an APC to stimulate a T cell reached the conclusion that a few to 100 cognate pMHC were sufficient to activate T cells (Demotz *et al.*, 1990; Harding and Unanue, 1990; Reay *et al.*, 2000; Sykulev *et al.*, 1996). These numbers were however based on an estimation of the average number of peptides on the APCs and using populations of T cells and APCs, leaving open the possibility that the actually activating APCs presented

Figure 5 Enhancement of signaling via TCR nanoclusters. Binding of a first cognate pMHC facilitates binding of a second cognate pMHC within a pMHC cluster, resulting in an apparent affinity that is higher than the sum of individual binding affinities (left panel). Binding of a pMHC cluster containing both cognate and self pMHCs to a TCR nanocluster permits spreading of TCR triggering to self-pMHC engaged TCRs (right panel).

more peptides than the average number. It was also known that soluble TCR triggering molecules, such as CD3- and TCR $\alpha\beta$ -specific antibodies and soluble pMHC complexes, need to be at least bivalent in order to be able to stimulate T cells (Boniface *et al.*, 1998; Kaye and Janeway, 1984). Extrapolation of these findings to the cognate pMHCs on APCs led to an apparent problem: how likely was it that two adjacent pMHC complexes would present the same, cognate peptide when only few cognate pMHC complexes were present amongst an overwhelming majority of self-pMHC complexes (Figure 6)?

Figure 6 Cognate pMHC distribution and valency of stimulatory ligands. Representation of the proposed problem of T cell activation depending on multivalent cognate pMHC interaction and the random distribution of cognate pMHC upon Ag-uptake (top panel) and experimentally supported solutions (bottom panel). Antigenic entity (e.g., bacterium, virus, and foreign protein) represented by magenta-colored hexagonal structure; cognate pMHC, self-pMHC with co-stimulatory capacity, and other self-pMHC represented by filled magenta circles, filled blue circles, and grey-lined open circles, respectively.

It was proposed that a cognate pMHC and an adjacent self-pMHC with some minimal TCR-binding capacity might, in combination with the co-receptor, form a pseudodimer that could activate the T cell (Irvine *et al.*, 2002). Artificial, antibody-based soluble pMHC pseudodimers were indeed shown to be able to activate T cells in a co-receptor-dependent manner (Krogsgaard *et al.*, 2005). On the other hand, recent work has shown that clusters of cognate pMHC are readily detectable on APCs that have been infected with virus or have internalized a foreign antigen (Bosch *et al.*, 2013; Ferez *et al.*, 2014; Lu *et al.*, 2012), suggesting that under physiological conditions pMHC is forming multivalent complexes and can therefore be ready to bind TCR clusters in a multivalent fashion.

A more recent study, analyzing pMHC number and T cell activation in single T cell-APC pairs, suggests that when incorporated in the plasma membrane one pMHC is indeed sufficient to induce a cytokine secretion response in both naïve and memory T cells (Huang *et al.*, 2013). This would implicitly mean that the currently held dogma that memory T cells are intrinsically more sensitive than naïve T cells is not correct. One caveat to these studies is the assumption that the technique employed to quantify the pMHCs on the cell surface is truly 100% efficient and that the tetravalent fluorescent probe used to detect the pMHCs recognizes them on a one-on-one basis under the conditions employed. In an alternative approach, using the arguably less physiological but more easily quantifiable SLB model, pMHCs were confined in artificial corrals whose size was much smaller than the T cell-SLB contact area (Manz *et al.*, 2011). It was found that, while keeping the pMHC density constant (and thus the total number of pMHC available for the T cell), distribution of the pMHCs in smaller and smaller corrals led to a point where having on average less than 2 pMHCs in a corral abrogated T cell activation. This suggested that the relevant signaling unit is a TCR cluster that would need more than one pMHC to become activated.

Conclusions

The past decade has seen important progress in understanding the molecular basis of TCR triggering. It has evolved from a very TCR $\alpha\beta$ -centered description to a much more integrated model of TCR triggering where we have started to define the domains and mechanisms involved in transmitting the pMHC-TCR $\alpha\beta$ interaction event to the intracellular domains of the CD3 dimers. In addition to affinity, we now have good evidence that conformational change, force, clustering, and relocation are critically involved in TCR triggering. Further molecular analysis of the mechanisms underlying these aspects of TCR triggering may provide us with new targets for therapeutic intervention. Part of these advances in our understanding have been obtained with classical biochemical and cellular approaches, but a strong boost has been given by the introduction of the super-resolution light microscopy and BFP techniques in the field. The challenge will be to integrate our knowledge on the separate parts into a single coherent mechanism of TCR triggering. This may ultimately need a crystal structure of the complete,

membrane-embedded TCR complex in presence and absence of its pMHC ligand.

Single Molecule Methods to Measure Receptor–Ligand Interaction in Immunological Synapses

JB Huppa, Medical University of Vienna, Vienna, Austria

Introduction

When measured in solution, T-cell antigen receptors (TCRs) bind their cognate ligand with surprisingly low affinity (micro molar range). Nonetheless, T-cells are exquisitely sensitive as they can sense the presence of even a single antigenic pMHC among thousands of structurally very similar but nonstimulatory endogenous pMHCs on the APC surface (Huang *et al.*, 2013). How is this possible? We think that much of the solution to this problem lies in studying TCR–pMHC in the right place, i.e. within the immunological synapse, the transient cell contact between a T-cell and a professional APC or target cell (Norcross, 1984) (reviewed in Bromley *et al.*, 2001; Huppa and Davis, 2003), to which T-cell antigen recognition is invariably linked.

Diversity of Immunological Synapses

This intercellular membrane structure was first resolved in its mature form, where it is highly organized with a bull's eye morphology (Monks *et al.*, 1998): its center, termed 'central supra-molecular activation cluster' (cSMAC), accumulates TCR-CD3 and is bordered by the ring-like 'peripheral supra-molecular activation cluster' (pSMAC), which contains the integrin LFA-1. An outer most ring harboring large glycoproteins such as CD43, CD44 and CD45 was later termed distal SMAC (dSMAC) (Johnson *et al.*, 2000; Leupin *et al.*, 2000). Depending on the interacting partners, immunological synapses are highly diverse in composition and function (reviewed in Friedl *et al.*, 2005) and therefore the term 'synapse' is nowadays used to describe any transient bi-membranous junction between T-cells and APCs (Huppa and Davis, 2003). The common denominator of all immune synapses is that they serve as a physical platform for one-on-one conversations between two conjugated cells: through engagement of cell-specific receptor–ligand pairs and directed secretion of effector molecules.

Molecular Size Hypothesis

Regardless of its physiology, each type of immunological synapse sets the stage for all interactions taking place within. While we know in considerable detail the biochemical and structural basis of many of such interactions in solution (Garcia *et al.*, 2009; Marrack *et al.*, 2008), the problem of how to place and evaluate them under the influence of their native environment is not trivial and far from being solved (for review see Dustin *et al.*, 2001). Synaptic binding is quite different from binding in solution in many respects. Molecular partners are pre-oriented on flexible surfaces, which can adjust their morphology in response to cell stimuli and acting forces.

This might greatly increase the on-rate of binding, but only if the two participating membranes are properly aligned. As was first proposed and experimentally pursued by Anton van der Merwe and Michael Dustin, molecular size is likely to influence binding significantly within the crowded synaptic confines (Irles *et al.*, 2003; Choudhuri *et al.*, 2005; Shaw and Dustin, 1997). This hypothesis is difficult to verify but is in line with theoretical predictions (Weikl and Lipowsky, 2004; Burroughs and Wulfig, 2002) and was recently even further supported by experiments involving a reconstituted T-cell-free cell system (James and Vale, 2012). In such artificial synapses the bulky and highly expressed protein tyrosine phosphatase CD45 was observed to be excluded from the more central parts of the cell contact only by means of its size. As a consequence CD45 had no longer access to its target, the much smaller TCR, which shifted the equilibrium toward TCR-CD3 complex phosphorylation driven by accessory kinases.

Forces Acting at Synapses

Cytoskeletal forces are also crucially involved in T-cell antigen recognition. Their existence is not only implied by membrane ruffling and a continuous flow of actin during synapse formation (Kaizuka *et al.*, 2007), but also by the energy-driven formation of TCR microclusters and their directed movement from the periphery to the cSMAC (Kaizuka *et al.*, 2007; Varma *et al.*, 2006). Depending on the strength of the antigenic stimulus and costimulation, synapse maturation – i.e. the concerted formation of cSMAC-, pSMAC- and dSMAC – occurs at a fast pace, i.e. within one to 30 min (Beemiller and Krummel, 2010; Beemiller *et al.*, 2012; Burkhardt *et al.*, 2008; Wulfig and Davis, 1998; Wulfig *et al.*, 2002). CD8⁺ cytolytic T-cells (CTLs) were even shown to rip off antigenic MHC class I molecules from the surface of the target cell (Huang *et al.*, 1999). Traction forces, which were measured on T-cells in contact with stimulatory arrays of antibodies reactive against CD3, reach up to 100 pN (Bashour *et al.*, 2014). Directly or indirectly, such forces may indeed influence the function of integrins such as LFA-1, which switch in response to pN-range shear forces from a low affinity to a high affinity conformation (Kong *et al.*, 2009).

Synaptic forces might also be instrumental to help the TCR and pMHC overcome steric barriers posed by larger proteins of the glycocalyx. However, they are also bound to destabilize low affinity interactions between TCR and pMHC. More stable TCR–pMHC interactions might just benefit from cellular motility due an increased on-rate, but weaker interactions could suffer considerably because of forbidding off-rates. Along this rationale, forces may well contribute to T-cell ligand discrimination merely by enforcing kinetic proofreading (Klotzsch and Schütz, 2013). Various lines of experimentation

even support the idea that forces acting directly on the TCR trigger T-cells through deformation of the TCR-CD3 complex (Kim *et al.*, 2009; Adams *et al.*, 2011; Lim *et al.*, 2012; Judokusumo *et al.*, 2012; Xie *et al.*, 2012).

Membranes Are Compartmentalized

It is exceedingly difficult to predict the effect of membrane compartmentalization on the TCR–pMHC binding dynamics. After all, the organization of plasma membranes is still controversially discussed (Simons and Gerl, 2010). However, several groups have reported the residence of TCRs and pMHCs in specific membrane microdomains (Lillemeier *et al.*, 2006; Schamel *et al.*, 2005; Williamson *et al.*, 2011). Live-cell high speed Photoactivation Localization Microscopy (hsPALM) studies designed to analyze the surface distribution below the diffraction limit of visible light revealed TCR-enriched domains of 20–70 nm in diameter (Lillemeier *et al.*, 2010). These entities were stable for several seconds, contained 1500 to 2200 TCR molecules per μm^2 , which were still mobile. Based on structural estimates a single TCR-CD3 complex covers roughly 40 nm² (Kuhns *et al.*, 2010). TCRs should therefore occupy between 6 and 9% of the surface accessible to them and bounce as a result into one another at random at a high frequency. Whether this might lead to the formation of higher order TCR structures with consequences for pMHC binding is still open to debate. Regardless of this issue, the mere existence of TCR- and pMHC enriched plasma membrane domains should affect the on-rate of TCR–pMHC binding, especially if both types of domains are properly aligned.

Measuring Binding *In Situ*

To validate synapse-specific parameters affecting TCR–pMHC binding there is no other way than to compare TCR–pMHC binding as it occurs *in situ* with that measured *in vitro*. The latter reveals binding properties inherent to the molecules under investigation. Surface plasmon resonance and to some extent calorimetry are the methods of choice. Deviations from binding *in vitro*, as they are found under defined synaptic condition, can then be used to assess synapse-specific impacts on binding. At current there are two experimental approaches for this. One involves a mechanical assay with single molecule resolution, the other single molecule fluorescence microscopy with the use of glass-supported artificial lipid bilayers (SLBs).

Mechanical Assays to Measure 2D-kinetics

One way to determine the 2-dimensional kinetics of TCR–pMHC binding was approached by Zhu and colleagues, who applied for this purpose the so-called adhesion frequency assay and a thermofluctuation assay (Huang *et al.*, 2010). Here, a T-cell aspirated to a micropipette is confronted with a pMHC-functionalized biomembrane force probe (BFP), either a red blood cell or a bead attached to the apex of a red blood cell. When the T-cell is displaced from the BFP either directly through translational movement away from the BFP (adhesion

frequency assay) or through random thermic motion (thermofluctuation assay), the BFP becomes briefly deformed as the result of molecular binding, which can be observed by conventional light microscopy. Remarkably, such deformations can be reflective of single TCR–pMHC bonds, and hence, on- and off-rates as well as the equilibrium constant of the binding process can be extracted for the special two-dimensional scenario, in which the aspirated T-cell contacts the BFP (see Figure 1).

Zhu and colleagues found for the OT-1 TCR system, that the stimulatory potency of pMHCs correlated very well with the measured 2D-affinity, which was actually much higher than would have been predicted based on 3D-binding measurements. An exceedingly high on-rate of binding caused this strong 2D-binding. Unexpectedly, the off-rate was found to be accelerated too, with agonist pMHC dissociating the fastest, i.e., more than 8000 times faster than when measured for 3D-binding.

Hence, the geometrical constraints appear to have a strong influence on the molecular dynamics of ligand interactions, and, at least in the case of OT-1 CD8⁺ T-cells, T-cell activation is likely caused by serial TCR engagement. Unlike what has been previously proposed based on 3D measurements, the stimulatory potency of the pMHC did not correlate with the drastically reduced stability of the TCR–pMHC complex. Such unexpected binding behavior must be reflective of T-cell-specific parameters, in particular the organization, orientation and also conformation of the TCR on the cell surface. These are not at all accounted for in 3D-binding assays involving purified soluble proteins, and hence have been largely ignored for this reason.

The use of wild-type MHC and a mutant, which is no longer capable of binding the CD8 coreceptor, allowed dissecting the contribution of CD8-MHC binding to TCR–pMHC binding (Jiang *et al.*, 2011). The kinetics of adhesion were found to proceed through two stages, one involving predominantly pMHC and the TCR followed by a second stage, which coincided with a marked increase in adhesion and which required both CD8-binding and the activity of its associated TCR-proximal tyrosine kinase LCK. This rapid increase in affinity is probably best explained through cooperative binding of TCR and CD8 to pMHC. If this holds true, then cell adhesion synergizes with the stimulatory potency of the pMHC–TCR engagement: more potent ligands would lead to a stronger participation of CD8 in the overall binding process. After all, this process might provide another means for ligand discrimination.

Imaging TCR–pMHC Interactions *In Situ*

Motivated for very similar reasons as Zhu and colleagues, we had devised a noninvasive ultrasensitive live-cell imaging approach to measure TCR–pMHC interactions in their native synaptic environment. Our methodology is based on single molecule microscopy and Förster resonance energy transfer (FRET) (Huppa *et al.*, 2010). FRET is a quantum-mechanical phenomenon involving the radiation-less interaction of dipole momenta of two corresponding fluorescent dyes (for a review on single molecule FRET see Ha, 2001). Because the maximal

Figure 1 Micropipette and bioforce probe measurements of 2D-binding constants. (a, b) Micrographs of the micropipette and bioforce probe (BFP) measurements. A T-cell (right) is aspirated by a pipette and aligned with a red blood cell held stationary by another pipette (left) without (a) or with a bead attached (b) to the apex. These experimental setups are employed to measure binding events as visualized by the deformation of the BFP in adhesion frequency assays (a) or thermofluctuation assays (b). The sensitivity of these systems reaches down to single TCR–pMHC bonds. (c) Scheme illustrating RBCs (left) are decorated via streptavidin with biotinylated monomeric pMHC to interact with TCRs on T-cells (right). Panels (a) and (b) reprinted by Huang, J., Zarnitsyna, V.I., Liu, B., *et al.*, 2010. The kinetics of two-dimensional TCR and pMHC interactions determine T-cell responsiveness. *Nature* 464, 932–936, with permission from Macmillan Publishers Ltd.

energy transfer rate is inversely proportional to the sixth power of the inter-dye distance, FRET efficiency can be used to assess whether and at what time two labeled proteins are interacting. We applied this methodology to detect and quantify TCR–pMHC binding events directly *in situ*. For this, 5c.c7 TCR transgenic helper T-cells were decorated with a site-specifically fluorescently labeled anti-TCR single chain fragment (FRET donor) and confronted with a functionalized fluid lipid bilayer, which served as a surrogate APC as it presents site-specifically labeled pMHC (FRET acceptor) as well as ICAM-1 and B7-1 (Figure 2).

Both, the choice of recombinant proteins as FRET partners, which were bioengineered to carry a fluorophore at a defined site, and the use of planar lipid bilayers as APCs proved essential for the success of the study. Planar supported lipid bilayers had been pioneered decades ago by Harden McConnell (Brian and McConnell, 1984) but were really brought to the attention of immunologists by Michael Dustin with the first spatiotemporal description of synapse formation and maturation (Grakoui *et al.*, 1999). Its use provides many operational advantages: it allows for the defined reconstitution of the APC membrane and reduces a three-dimensional problem to two dimensions, thereby enabling the recording of fast and transient processes such as TCR–pMHC binding. Importantly, planar bilayers are compatible with total internal reflection microscopy (TIRF), which reduces background fluorescence substantially (Axelrod, 2008). Prior to our study, TIRF microscopy had helped to visualize the synaptic formation of synaptic entities, such as TCR microclusters, and to deduce

cell-biological mechanisms underlying synaptic signaling (Campi *et al.*, 2005; Varma *et al.*, 2006; Yokosuka *et al.*, 2005; Bunnell *et al.*, 2006; Huse *et al.*, 2007). In our study TIRF microscopy improved the signal to noise ratio to such an extent that we could resolve single fluorophores and single molecule FRET events and track individual pMHC–TCR interactions over time.

By doing so we found that, compared to solution binding, synaptic binding of the TCR was significantly increased in strength with both an accelerated association (about 100-fold) and an accelerated dissociation (about 4–12-fold) (Huppa *et al.*, 2010). Interestingly, depolymerization of the T-cell's cortical actin resulted in a remarkable stabilization of synaptic TCR–pMHC complexes, an observation that implicates mechanical cellular forces in disrupting TCR–pMHC complexes. It is conceivable that such forces indeed contribute to TCR–ligand discrimination and to TCR-proximal signaling for reasons discussed below.

In agreement with previous studies, addition of a CD4 blocking-antibody interfered with TCR-proximal signaling at all times, yet had, in contrast to CD8 blockade on CTLs, only a minor effect on the TCR–pMHC interaction. Hence, other avenues, for example the visualization of CD4–MHC interactions, will be needed to shed light on the enigmatic mechanism, by which CD4 boosts T-cell sensitivity.

We complemented our FRET study using single molecule tracking of fluorescently labeled pMHC (Axmann *et al.*, 2012). Individual pMHC molecules were recorded as they moved via Brownian motion within the synapse, with occasional stops

Figure 2 Förster resonance energy transfer (FRET)-based methodology (a, b) and single molecule tracking of fluorescently labeled pMHC (c) to measure TCR–pMHC interaction within the immunological synapse. (a) Shown is a composite model of the FRET system based on the TCR–pMHC and TCR–H57 Fab structures. The TCR is shown in blue, the MHC molecule in red, the peptide in yellow, and the scFv in light brown. The distance between the Cy5 (alternatively Alexa Fluor 647, FRET acceptor) attachment site (red) and the Cy3 (alternatively Alexa Fluor 555, FRET donor) attachment site is about 41 Å, less than the Förster radius of the Cy3–Cy5 (Alexa Fluor 555–Alexa Fluor 647) system, the distance of half-maximal energy transfer. (b) Schematic illustration of the experimental setup: TCR-transgenic T-cells interact with a planar glass-supported lipid bilayer, which harbors B7-1 (costimulator), ICAM1 and site-specifically labeled pMHCs. A FRET signal can only be produced when TCR and pMHC are close enough to bind to each other. The use of planar lipid bilayers allows the application of total internal reflection fluorescence microscopy (TIRF), in which only a thin slice of the T-cell contacting the bilayer (about 100 nm in thickness) is illuminated, which reduces background fluorescence substantially. (c) Illustrated is the rationale underlying the single molecule tracking approach to measure TCR–pMHC interaction times. Compared to bilayer-embedded pMHCs, T-cell-associated TCR–CD3 complexes diffuse laterally with a ~ 10 -times lower diffusion constant D . As a consequence fluorescence-labeled pMHCs slow down significantly in their lateral movement when they bind to a TCR. We have exploited this property to determine TCR–pMHC off-rates in the synaptic 2D-case.

due to binding to the TCR at the opposing T-cell surface. We quantified the immobilization lifetimes, which yielded similar interaction durations as those determined via the FRET-based method. This was *a priori* not expected, as pMHC rebinding to different TCRs in the immediate vicinity – for example, within a TCR microcluster – would have prolonged the detected pMHC immobilizations. Together, the two data sets thus indicate that – at least under the applied conditions of

high TCR–pMHC interaction probability – immediate pMHC rebinding does not occur at statistically relevant levels.

There are more implications associated with the results of our studies: first, interactions between TCRs and endogenous ligands in the periphery and within the thymus, which are too weak to be detected *in vitro*, could indeed occur in the synapse. And secondly, in light of the synaptic geometry and its influence on molecular interactions, the degree, to which low

affinity interactions take place in the synapse, is no longer only encoded within the molecular properties of the two binding partners involved but might very well depend on the properties and behavior of the two conjugated cells. Consequently, synaptic binding can no longer be comprehensively expressed with one single binding constant (as is the case for *in vitro* studies) but only described with the use of effective parameters, which are valid in a given synaptic region at a given time. The latter point is especially emphasized in our FRET-based study: TCR affinity varied substantially, that is up to 250-fold, within different synaptic regions and also between different cells. In other words, TCR–pMHC binding, and probably all other interactions of low to moderate strength, if not the entire process of antigen recognition are controlled through not well-understood cell biological and cellular parameters, which could also be regulated in T-cell development, in response to environmental cues and under disease conditions.

It should be noted that a recent publication from the Groves lab challenged the view of increased TCR–pMHC unbinding kinetics (O'Donoghue *et al.*, 2013): in their study, O'Donoghue *et al.* also employed single molecule tracking of fluorescently labeled pMHC in T-cell synapses with functionalized SLBs, however, they used rather long illumination times so that only bound pMHC molecules were imaged as individual spots, whereas unbound molecules generated a rather homogeneous background. From their data, the lifetime of pMHC immobilizations could be directly determined by

measuring the observation time of the spots, yielding approximately 30-fold slower interaction kinetics than our single molecule FRET and tracking data. At this stage, it is difficult to clarify this discrepancy: it may involve different stimulation conditions, or the presence of statistical subsets of TCR–pMHC pairs with different unbinding kinetics.

Pulling Forces Enhance Discriminative Power of Peptide Recognition

As outlined above, the two-dimensional cell-to-cell interface within the synapse not only affects the on-rate of protein–protein trans-interactions, but – due to pulling forces – also the off-rate. It is surprising that pulling forces have hardly been recognized as modulators of binding properties of cell surface receptors in general, given the large amount of literature on adhesion receptors (for review see e.g., Evans and Calderwood, 2007). Dembo *et al.* first discussed how pulling may either strengthen or weaken a bond, giving rise to the terminology ‘catch bonds’ versus ‘slip bonds,’ respectively (Dembo *et al.*, 1988) (Figure 3). Various conceptual models were proposed for catch-bond behavior (Thomas *et al.*, 2008); the most intelligible concept may be the hook model, in which receptor and ligand are connected like two hooks: with increasing force, the bond tightens and the bond lifetime gets prolonged. In contrast, slip bonds break with increasing force. This behavior can be best explained by a force-induced reduction of the

Figure 3 Effect of forces on receptor–ligand unbinding. The top row shows in a cartoon how cell surface receptors may contact each other, the bottom row the according energy landscape. In case of slip bonds (left), pulling forces reduce the activation energy for unbinding, E_a , thereby reducing the average bond lifetime. In contrast, catch bonds (middle) lead to an increase in the activation energy, so that the binding tightens. Such behavior can be explained, for example, by a hook-model, as indicated in the sketch above. Catch-slip bonds (right) show catch-bond behavior at low forces, and slip bond behavior at high forces. In that case, two force-dependent unbinding pathways have to be considered: at low forces, the catch-bond behavior is dominant ($+\Delta E_a$; unbinding to the left in the energy diagram), whereas at higher forces the slip bond behavior gets dominant ($-\Delta E_a$; unbinding to the right).

activation barrier, so that the average bond lifetime is decreased. Also two-pathway models are discussed, for example, with catch-bonds behavior at low forces and slip bond behavior at high forces (catch-slip bonds) (Thomas *et al.*, 2008). Indeed, for the TCR–pMHC interaction both catch bond and slip bond behavior has been reported (Robert *et al.*, 2012; Liu *et al.*, 2014).

Force-induced unbinding makes it thus essentially impossible to predict kinetic rate constants from *in vitro* experiments: the obtained values may be too short in case of catch bonds, or too long for slip bonds. Quantitatively, the effect on particular receptor–ligand pairs may vary substantially for different peptides, with up to 10-fold accelerated or decelerated kinetics being absolutely possible (Klotzsch and Schütz, 2013).

In the kinetic proofreading model, TCR–pMHC bond lifetimes determine the degree of ITAM phosphorylation, and thus ultimately the activation state of the T-cell. Force modulated unbinding could thus influence the power of ligand discrimination: At the extreme, two different TCR–pMHC bonds – a catch bond and a slip bond – with identical off-rate at zero force will separate into a high off-rate and a low off-rate bond at high force. Indeed, Liu *et al.* reported differential behavior of agonistic peptides (catch-slip bonds) and antagonistic peptides (slip bonds) for CD8⁺ T cells (Liu *et al.*, 2014). Pulling forces thus can generate additional contrast in the rupture behavior of different peptides.

We recently raised the question whether force-induced unbinding may also improve the specificity of pMHC discrimination in case of slip bonds (Klotzsch and Schütz, 2013). Our rationale was inspired by rupture curves of receptor–ligand pairs recorded via atomic force microscopy. In such experiments, force ramps of constant pulling velocity are applied, which result in the continuous reduction of the activation barrier and a concomitant increase in unbinding probability. The effect on the statistics of the bond lifetimes is dramatic: without force an exponential lifetime distribution is obtained; the pulling results in a pronounced peak of the lifetime and a steep slope toward higher values. In other words, higher lifetimes than the peak are extremely rare. This curve shape makes discrimination extremely reliable, with false positives being highly unlikely.

Conclusion and Outlook

We have made a case that synaptic receptor–ligand binding dynamics are not merely governed by structural and biochemical properties of the binding partners involved. *In situ* interactions are moreover subjected to geometrical constraints present in the narrow synaptic cleft and also to cell-biological parameters controlled by the conjugated cells. This means that the decision whether a T-cell remains quiescent or whether it becomes activated – especially when faced with few antigenic pMHCs – depends not only on the pMHC identity but also on the cell surface context, in which TCRs are active and their ligands are expressed. We anticipate, that the single molecule studies presented herein are only the beginning of an exciting scientific expedition into the synaptic ‘nanocosm,’ a journey, which is ultimately driven by the quest for understanding the foundation of the phenomenal T-cell antigen sensitivity.

In addition to what we have discussed above, a number of factors come immediately into mind: cell adhesion, costimulation, the nanoscale organization of TCRs, pMHCs and accessory factors within the plasma membrane are likely to alter the TCR–pMHC binding dynamics and hence T-cell antigen sensitivity. The action of sugar-binding galectins and posttranslational modification of N-linked glycans, a self-remodeling cytoskeleton and co-expression of membrane-organizing elements such as tetraspanins could well influence membrane architecture and consequently antigen recognition. The extent to which such factors matter can only be determined through experimental work, in which we deem single molecule microscopy to be instrumental.

Single-Cell Interrogation of the Immune System Using Microtools

C Albayrak and S Tay, ETH Zürich, Basel, Switzerland

© 2016 Elsevier Inc. All rights reserved.

The immune system comprises a highly complex and dynamic network of different cell types, and it negotiates responses to a vast array of challenges over different time scales (Brennan *et al.*, 1989; Egen *et al.*, 2008; Shulman *et al.*, 2013). As such, studying the immune system necessitates technologies with high sensitivity, resolution, and throughput commensurate with its complexity and dynamic nature (Junkin and Tay, 2014). Furthermore, biological systems including the immune system are inherently noisy. Measurements from bulk populations (which amount to ensemble averages) mask the underlying intercellular heterogeneity that arises either from stochasticity of processes such as binding events (intrinsic noise, e.g., RNA polymerase binding to its promoter) or from variations in levels of auxiliary factors that indirectly affect that process (extrinsic noise, e.g., differences in ribosome or chaperone concentrations) (Eldar and Elowitz, 2010; Elowitz *et al.*, 2002). This heterogeneity underlies important biological phenomena such as T cell response to vaccines (Flatz *et al.*, 2011) and nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) activation dynamics (Tay *et al.*, 2010), among others. Single-cell analysis will thus lead to a more complete and accurate understanding of immune cell dynamics, i.e., how individual cells in the immune system interact to create the observed phenotypes. In this brief article, we will summarize the relevant advances in microscale technology for studying immune cell activities, such as secretion, migration, and intercellular communication, at the single-cell level.

Single-Cell Secretion

Both integrated microfluidic devices (Araci and Quake, 2012; Thorsen *et al.*, 2002) and well arrays have been used for secretion analysis and selection of single cells. Well arrays are typically used in one of two configurations: (1) open configuration, where the secreted proteins are captured on the functionalized well surface, and (2) closed configuration, where the well surfaces are inert (with respect to protein-protein interactions), and the secreted proteins bind the functionalized glass lid. The latter approach, also called microengraving, enables repeated interrogation of the secreted proteins using multiple lids and separate analyses of the captured single cells and the lids.

The single-cell barcode chip (SCBC) developed by the Heath group is one example of an integrated microfluidic device for quantifying single-cell secretion. The device contains 1040 microchambers, each of which can hold one or several cells and contains immobilized primary antibodies that can bind up to 12 different antigens. Each primary antibody is covalently coupled to a different single-stranded DNA oligomer (Bailey *et al.*, 2007); these oligonucleotide-antibody conjugates are then flowed in microfluidic channels (a

different bioconjugate in each channel) over immobilized DNA oligomers with complementary sequences (Fan *et al.*, 2008). The primary antibodies are thus spatially patterned in stripes (hence the name, the 'barcode' device), and secreted proteins are quantified by measuring fluorescence intensity from the immune sandwich assays (Ma *et al.*, 2011; Figure 1(a)). The SCBC was used to compare the secretion profile of various single antigen-specific cytotoxic T lymphocytes (CTLs) sourced from healthy donors and a metastatic melanoma patient; up to 45 functional CTL subpopulations were identified by grouping cells that secreted the same proteins (Ma *et al.*, 2011). The SCBC was also used in conjunction with information theory-based entropy analysis to first construct a covariance matrix that reproduces fluctuations observed in secretions of unperturbed single macrophages, and then successfully predict perturbations in secreted protein levels due to neutralizing antibody treatment or the presence of multiple secretory cells (Shin *et al.*, 2011). Variations (e.g., the nanowire chip, pin-spotted arrays) and improved versions of the SCBC were later reported (i.e., higher throughput and degree of multiplexing) (Elitas *et al.*, 2014; Kwak *et al.*, 2014; Lu *et al.*, 2013); a most recent report features a device that can detect as many as 42 proteins secreted from single macrophages using antibodies distinguishable by both location and fluorophore color (Lu *et al.*, 2015).

Drop-based microfluidic devices have also been used for single-cell secretion analysis. Fluidic control and device manufacture are considerably simpler than integrated microfluidic devices, and single-cell isolation within drops enables higher assay throughput. Emulsification speed and assay (drop) volume can be easily modified by adjusting the flow rates of the aqueous and oil streams. This method is more suitable for batch assays, however, since controlled fluid addition to or perfusion of drops after emulsification is technically challenging. For example, a drop-based device enabled the monitoring of both surface marker CD86 (cluster of differentiation 86) production and interleukin 6 (IL-6) secretion from single dendritic cells for over 2 h using fluorescently tagged antibodies (Konry *et al.*, 2013). In an earlier study, IL-10 secretion from single T cells was analyzed by encapsulating them with beads displaying fluorescent capture antibodies (Konry *et al.*, 2011). An interesting variation was recently reported by Chokkalingam and colleagues, who captured the molecules secreted by individual Jurkat cells in agarose beads suitable for conventional flow cytometry. As in mentioned examples, single cells are encapsulated in drops with antibody-displaying beads and, crucially, ultra-low temperature gelling agarose. Upon cooling to 4 °C, the agarose gels and forms a bead that captures the secreted molecules along with the single cell; these beads are then washed, interrogated with fluorescent antibodies, and analyzed by flow cytometry (custom in-device cytometry is not needed since oil no longer comprises the continuous phase). Different groups of cells secreting IL-2,

interferon gamma (IFN γ), tumor necrosis factor alpha (TNF- α), and their combinations were identified (Chokkalingam *et al.*, 2013).

Open well arrays constitute an easily operable system and enable experimentation with and processing of hundreds of single cells. Capture reagents (i.e., typically antibodies specific to the secreted analytes) are immobilized at the bottom of the well array, and single cells are deposited in microwells. Once captured, single cells can be stimulated and the secreted molecules quantified by fluorescence (Zhu *et al.*, 2009). The immunospot array on a chip method pioneered by the Muraguchi group enables simultaneous detection of single antibody-secreting cells (ASCs) in $\sim 230\,000$ wells within several hours; antigen-specific ASCs can then be recovered, and the monoclonal antibodies obtained by subsequent cloning in a week (Jin *et al.*, 2011, 2009; Figure 1(b)).

Aptamers have also been used as capture reagents in microfluidic well arrays to detect secreted molecules. In this 'aptasensing' method, a redox reporter is covalently attached to the aptamer, and the aptamer specific to the secreted molecule is immobilized on miniature electrodes. Secreted cytokines lead to a conformational change in the aptamer upon binding, which leads to a change in the recorded current (Liu *et al.*, 2011; Figure 1(c)). Unlike antibody-based detection, this method does not need washing and rebinding of the analyte for multiple detections, thereby increasing time resolution of a kinetic secretion study. Liu *et al.* (2015, 2012) were able to monitor TNF- α and IFN- γ secretion from several hundred cells over 2–4 h with 20-minute time resolution. However, single-cell resolution is yet to be demonstrated; cytokine secretion from as low as 90 cells could be detected by aptasensing (Liu *et al.*, 2011).

Microengraving was originally demonstrated by Love and colleagues as a fast and high-throughput method for screening and isolation of ASCs. Individual cells could be viably captured in printed wells by limiting occupancy (i.e., using Poisson distribution), grown in the 0.1–1-nl wells, and their antibody secretions captured on glass lids functionalized either with the cognate antigen or secondary antibody (Bradshaw *et al.*, 2008; Love *et al.*, 2006; Story *et al.*, 2008; Figure 1(d)). Dense packing of wells increased throughput, while volume miniaturization drastically reduced the number of molecules required to beat the affinity threshold for efficient non-

covalent capture of secreted antibodies, and thus overall duration and cost of the screen. The supernatant can be sampled multiple times to monitor single-cell secretion over time (Han *et al.*, 2010). By measuring single-cell cytokine secretion every 2 h, researchers showed that stimulated T cells predominantly secrete cytokines one at a time as opposed to secreting multiple molecules simultaneously (Han *et al.*, 2012). Microcapillary arrays (i.e., the DiCAST platform (Fitzgerald *et al.*, 2015)) further increase screening capability by enabling interrogation of single-cell secretions using two functionalized lids simultaneously (rather than one as in microengraving). Many microcapillaries ($\sim 10^6$) with open top and bottom surfaces were densely packed in an array; proteins secreted by single cells in these capillaries queried using dual antibody-containing lids; and the desired cells subsequently recovered by automated analysis and pneumatic tools. Using this high-throughput method, antigen-specific hybridoma cells could be recovered without cloning by limiting dilution (Fitzgerald *et al.*, 2015).

Cell Migration

Microfluidic gradient devices coupled with time-lapse microscopy enables the study of single-cell migration under various chemokine gradients. Earlier designs depended on continuous flow to generate gradients, where solutions containing different chemokine concentrations were flowed side-by-side in a laminar regime. Cell migration is observed under flow in response to the transverse chemokine gradient. One of the earliest flow-dependent gradient devices was reported by Dertinger *et al.* (2001), and was used to study single neutrophil chemotaxis in different IL-8 gradients (Li Jeon *et al.*, 2002; Figure 2(a)). The device contains a branching network of serpentine channels that alternate with single wide channels where the gradients are formed perpendicular to the direction of laminar flow. The number of serpentine channels increases downstream, thereby enabling the formation of smooth linear gradients; the numbers of branching channel networks and liquid inlets can also be modified to create gradients with more complex shapes (Dertinger *et al.*, 2001). In this gradient device, the response of individual neutrophils to complex IL-8 gradients was traced. The neutrophils overshot the maximum

Figure 1 Microfluidic methods for measuring single-cell secretion. (a) Single-cell barcode chip (SCBC). IL-8 concentration in a gentle (hill) gradient, but did not overshoot when the IL-8 concentration decreased abruptly (i.e., in a cliff gradient), thereby demonstrating their ability to respond to complex chemotactic cues (Li Jeon *et al.*, 2002). These cells were later shown to oscillate in their migration direction under flow when placed in opposing gradients of IL-8 and leukotriene B4 (LTB₄), both of which lie below formyl-methionyl-leucyl-phenylalanine (fMLP) in signaling hierarchy (Byrne *et al.*, 2014).

Flow-dependent gradient devices are inherently limited, however, since continuous flow is required to maintain the

chemokine gradient and may itself perturb cell migration and signaling (Walker *et al.*, 2005), thereby introducing additional variables unrelated to cell physiology. Flow-free devices were thus used by us and others to study immune cell migration under various scenarios; gradients in these devices are established by diffusion between solutions with and without the chemotactic agent (i.e., source and sink). For example, our group recently reported a modular gradient device that can generate up to 10 different programmable gradients in triplicate by alternating flow in the source and sink channels across a total of 30 chambers (Frank and Tay, 2013; Figure 2(b)).

Unlike in flow-dependent gradient devices, the absence of cross-flow in this device enables the observation of single or multiple cells in suspension and communication between individual cells via secreted factors. A different flow-free gradient device was used by us to study migration of single human T cells under a CXCL12 (chemokine (C-X-C motif) ligand 12) gradient. This device used a similar source-sink configuration, but enabled the retrieval of cells with different chemotactic characteristics (fast vs. slow, migrating vs. stationary; **Figure 2(c)**). Integrated analysis of the single T cells revealed that ones that migrate strongly in a CXCL12 gradient had elevated levels of CXCL4 (chemokine (C-X-C motif) ligand 4) expression (**Mehling et al., 2015**). **Keenan et al. (2006)** designed a flow-free gradient device (i.e., the Microjets device) to study neutrophil desensitization, the process by which neutrophils distinguish different chemotactic cues and respond to ones that take them to the infection or damage site effectively; fluorescent dyes were mixed in the chemokine solutions to simultaneously verify gradient profiles. Different subsets of neutrophils were identified based on their migration behavior (**Keenan et al., 2010**).

Three-dimensional (3D) gradient devices contain a gel matrix between the source and sink compartments and thus better mimic a tissue microenvironment by allowing the cells to migrate within the matrix in 3D. **Abhyankar et al. (2008)** designed a 3D gradient device, where two reservoirs are placed at opposite ends and on top of a 3D collagen gel. A steady gradient can be maintained by replenishing the solutions in the reservoirs, and chemotaxis of individual neutrophils in a temporally evolving fMLP gradient was quantified. Haessler and colleagues reported another device, which contains a biological extracellular matrix in a channel between the source and sink channels (**Figure 2(d)**). Dendritic cells were observed to preferentially migrate toward a CCL21 (chemokine (C-C motif) ligand 21) rather than a CCL19 (chemokine (C-C motif) ligand 19) gradient in the 3D environment, both of which bind CCR7 (chemokine (C-C motif) receptor 7) with

similar affinity (**Haessler et al., 2011**). This preference was also observed in T cells under flow (**Nandagopal et al., 2011**).

Microfluidic devices with small channels were also employed to reveal more complex migration behavior. For example, single T-lymphocytes migrated upstream on flow microchannels coated with ICAM-1 (intercellular adhesion molecule 1), but downstream on ones coated with vascular cell adhesion protein 1 (VCAM-1), and they preferred to migrate upstream when under increasing shear rate (**Dominguez et al., 2015**). **Sundt et al. (2012)** studied neutrophil rolling under high shear stress, observed the formation of slings (i.e., long cell protrusions) downstream in the direction of flow, and postulated that these slings originate from tethers behind the cell and appear in front as a result of neutrophil rolling. The slings also stabilize neutrophil rolling under high shear stress conditions such as in acute inflammation. In a separate study, forward and reverse migration (retroaxis) of individual neutrophils were quantified using a microfluidic device with U-shaped channels under various chemokine gradients; cells displayed three different retroaxis phenotypes (**Hamza et al., 2014**). **Boneschansker et al. (2014)** used a flow-free microfluidic device with cell traps to quantitatively study neutrophil and lymphocyte migration. Once trapped, individual cells could either migrate toward or away from the chemokine in narrow microfluidic channels; the direction, speed, persistence, and percentage of motile cells were quantified from time-lapsed images, thereby yielding a more comprehensive picture of cell migration in chemokine gradients. Jones and colleagues mimicked a focal inflammation site using a microfluidic device, where focal chemotactic chambers (FCC) that simulate foci of inflammation were connected by narrow channels to a central cell loading chamber (CLC). The CLC also acted as a sink for the chemokines diffusing from the FCC. Cells that chemotactically migrated toward the FCC could be distinguished from those exhibiting chemokinesis by the bifurcation in the small channel; the former would only follow the migration channel, while the latter would follow both

migration and exit channels (Figure 2(e)). A fluorescent elastase assay was implemented in-chip to distinguish inflammation-induced recruitment of monocytes, in which elastase is up-regulated. This microfluidic setup enabled the researchers to obtain a more comprehensive understanding of the inflammation scenario in the presence of different leukocyte subpopulations, chemoattractants and other inflammation-mediating agents (Jones *et al.*, 2012). In addition to these devices, the automated cell culture chip (Gomez-Sjöberg *et al.*, 2007) was used by us to quantitatively analyze fibroblast migration in a population context, but on a single-cell level (Figure 2(f)). Cell motility was observed to be influenced by both internal factors such as directional bias of pseudopod formation and social factors such as intercellular collisions and secreted chemokines (Vedel *et al.*, 2013).

Finally, several reports were focused on simplifying the implementation of these microtools for cell migration studies, thereby making them accessible to a broader group of researchers. For example, Sackmann *et al.* (2012) developed the kit-on-a-lid-assay (KOALA) that can be conducted with only a micropipette and an optical microscope; migration of individual primary neutrophils was studied using a few microliters of blood. Wu *et al.* (2014) reported the USB microscope-based microfluidic chemotaxis analysis system (UMCAS) that automates cell tracking analysis and provides quantitative cell migration data. Sip *et al.* (2014) designed a simple microfluidic transwell insert for standard 6-well plates that can generate a stable gradient over a large portion of the well surface area. Chemotaxis of individual HL-60 cells due to an fMLP gradient in a conventional well plate could be quantified using this microfluidic insert and time-lapse microscopy. Examples such as these will hopefully facilitate the adoption of these powerful microtools by researchers not specialized in microfluidics.

Cell-Cell Communication

In this context, microfluidic devices have been used to analyze interactions (via direct contact or paracrine signaling) between different cell types on a single-cell level or to capture the physiological complexity within a more simplified experimental setting by mimicking *in vivo* scenarios (e.g., tumor microenvironments, blood vessels).

We have recently designed an integrated coculture device that ensures precise control of intercellular communication via paracrine molecules (Figure 3(a)). First and second responder cells (macrophages and fibroblasts, in this case) were cultured in adjacent chambers; each of these chambers could be independently fed and washed; and intercellular communication via paracrine signaling was permitted by opening the valve that divides the adjacent culture chambers. Single or multiple macrophages were stimulated by bacterial lipopolysaccharide (LPS); single or multiple fibroblasts were exposed to the TNF- α secreted by macrophages upon LPS activation; and nuclear localization of NF- κ B in individual fibroblasts was measured by fluorescence microscopy (Frank and Tay, 2015). Another recent study by Shalek and colleagues used Fluidigm's C₁ single-cell capture device with single-cell RNA sequencing to study the effect of paracrine signaling on the response of primary dendritic cells to different pathogenic components. The C₁ device

allowed the researchers to stimulate individual dendritic cells in isolation and compare these to cells collectively stimulated in a test tube, thereby decoupling the effects of paracrine agents from those of other factors (Figure 3(b)). The researchers discovered a small subset of 'precocious' dendritic cells that first express antiviral genes and activate these genes in other cells by IFN- β signaling, thereby mounting a population response. This is followed by a second wave of paracrine signaling independent of the initial IFN- β that downregulates the inflammatory genes (Shalek *et al.*, 2014). Elitas and colleagues compared the profile of secreted proteins from cocultures of glioma cells and macrophages to those from single glioma or macrophages; 16 secreted proteins were quantified using a barcode chip (Lu *et al.*, 2013). Statistically significant differences between the coculture secretion profile and the synthetic addition of secreted protein profiles from individual cell types indicated paracrine effect (Elitas *et al.*, 2014). The aptasensing platform was also used to analyze paracrine communication between different groups (active and quiescent) of monocyte-like cells via cytokines. About 600 cells were captured in microwells, and the researchers were able to quantify the TNF- α secreted by different cell groups and calculate secretion rates (Kwa *et al.*, 2014).

Kim and Haynes used a flow-dependent device to investigate single neutrophil chemotaxis and migration on endothelial cells, which mimicks neutrophil movement in blood vessels prior to extravasation. The presence of endothelial cells and molecules expressed by these cells (such as surface adhesion molecules CD11b (cluster of differentiation 11b, also known as integrin alpha M (ITGAM)) and CD66b (cluster of differentiation 66b, also known as carcinoembryonic antigen-related cell adhesion molecule 8 (CEACAM8))) drastically altered the migratory behavior of neutrophils, demonstrating the importance of cell-cell interactions in neutrophil migration (Kim and Haynes, 2013). In the same vein, Mahmood and coworkers analyzed migration of single natural killer (NK) cells in dendritic cell (DC)-conditioned medium, which mimics the presence of DCs and NK cells in the same microenvironment. The DC-conditioned medium (containing factors secreted by DCs) increased NK cell chemotaxis, and this chemotactic activation was partially dependent on CXCR3 (Chemokine (C-X-C motif) receptor 3) signaling (Mahmood *et al.*, 2014). Immunological synapse formation between mature DC and T cells were analyzed on a single-cell level using a drop-based device. The two cells were encapsulated together in drops, and cytoskeleton remodeling and tubulin polymerization could be observed upon contact between mature DC and T cells (Konry *et al.*, 2013).

Lytic interactions between two different cell types were also investigated using microfluidics. Varadarajan and colleagues used microengraving to analyze both secretion and cytolytic activity of CD8⁺ T cells from HIV-infected patients on a single-cell level. Their high-throughput analysis showed that when T cells encounter viral antigen presenting cells (APCs), a majority of them either secrete IFN- α or lyse their targets, but not both (Varadarajan *et al.*, 2011). Other microfluidic studies on NK cells revealed more single-cell heterogeneity in their interactions with target cells. For example, a small subset of IL-2-activated NK cells in the studied population killed the majority of target kidney cells; these 'serial killer' cells were larger than others and induced fast necrotic cell death

Figure 3 Intercellular communication at the single-cell level. (a) One functional unit of our new coculture device. Each cell (A and B) can be fed and washed independently, and the separation valve can be opened to trigger intercellular communication. (Adapted from Frank, T., Tay, S., 2015. Distinct migration and contact dynamics of resting and IL-2-activated human natural killer cells. *Frontiers in Immunology* 5, 80. © 2014 Olofsson, Forslund, Vanherberghen, Chechet, Mickelin, Ahlin, Everhorn and Önfelt.)

(Vanherberghen *et al.*, 2013). They also seem to spread over their targets upon contact (Olofsson *et al.*, 2014). In contrast, resting NK cells were less mobile and less lethal, formed fewer contacts with target kidney cells, and maintained their spherical shape upon contact (Olofsson *et al.*, 2014; **Figure 3(c)**). An earlier study utilizing microwell arrays also revealed that individual IL-2-activated NK cells secreted MIP-1 β and TNF- α upon contacting target cells (Yamanaka *et al.*, 2012).

Other Applications

Medical Applications: Microtools as Part of an Integrated Workflow

The mentioned examples utilized microtools to reveal different aspects of immune cell physiology on a single-cell level.

However, microfluidic devices can also comprise a powerful unit in an integrated workflow; they can either be used to screen and identify desired cells in a high-throughput fashion or to analyze them on a single-cell level after selection. Unlike methods such as intracellular cytokine staining (ICS) (Jung *et al.*, 1993), single cells can be evaluated in these devices and desired ones later recovered for further characterization (Varadarajan *et al.*, 2012). For example, Ogunniyi and colleagues combined microengraving with on-device cytometry and single-cell RT-PCR to profile immune cells from HIV patients. Plasma cells and memory B cells were scored in parallel for viability, marker phenotype, and secreted antibody isotype and specificity; some cells were later recovered for RT-PCR and sequencing of the antibody-encoding genes (Ogunniyi *et al.*, 2014). In another study, researchers combined microengraving with whole-exome sequencing to determine somatic

single-nucleotide variants (SSNVs) among circulating tumor cells (CTCs) and compare the mutations in CTCs to those from different tumors of a single patient with metastatic prostate cancer (Lohr *et al.*, 2014).

Microfluidic tools were also used in one recent study, where isolating and singly analyzing rare cell populations revealed new disease mechanisms and therapeutic target molecules. Zhou and colleagues identified immunotherapy targets by administering a small hairpin RNA (shRNA) library and sequencing ones that enable T cell proliferation *in vivo* in the tumor microenvironment. After discovering *Ppp2r2d* as a potential target, the researchers used a well array to analyze at a single-cell level the cytokines secreted by *Ppp2r2d*-silenced T cells harvested from a melanoma tumor (Zhou *et al.*, 2014).

Dissecting Biological Noise

One of the greatest contributions of single-cell analysis has been in the discovery and analysis of biological noise (Elowitz *et al.*, 2002; Figure 4(a)). Traditional bulk measurements

inherently overlooked this fundamental aspect of biology, since they represent averages of isogenic yet fluctuating cells. Microfluidics and fluorescence microscopy have been used by us and others to facilitate high-throughput interrogation of signaling pathways at the single-cell level.

Our group has learned much from single-cell analysis of the NF- κ B signaling pathway, dysfunction of which plays a role in inflammation, immune diseases, and cancer (Courtois and Gilmore, 2006). In a new study, Kellogg and Tay used an integrated valve-based microfluidic device (Gomez-Sjöberg *et al.*, 2007) to study NF- κ B expression in hundreds of individual mammalian cells for >20 h under various stimulation scenarios (sustained vs. oscillating input) and understand how noise and input oscillations affect signal transduction (Kellogg and Tay, 2015; Kellogg *et al.*, 2014; Figure 4(b)). Nuclear NF- κ B oscillations were entrained (i.e., phase-locked with input oscillations) or disrupted depending on the oscillating input period, which affected expression of NF- κ B target genes; entrained NF- κ B oscillations led to higher levels of target expression. Both single-cell kinetic data and simulations based on a hybrid NF- κ B model

Figure 4 Biological noise and its consequences. (a) Intrinsic noise leads to differential expression of red and green fluorescent proteins, resulting in a heterogeneous population of isogenic bacteria. (b) Members of a noisy cell population will also process a given signal (input) differently and exhibit a wide range of responses (output). (Reprinted with permission from Elowitz, M.B., Levine, A.J., Siggia, E.D., Swain, P.S., 2002. Stochastic gene expression in a single cell. *Science* 297, 1183–1186. © 2002 American Association for the Advancement of Science.) (c) Roles of intrinsic and extrinsic noise in transcriptional control and signaling dynamics. Intrinsic noise increases NF- κ B oscillation and entrainment (which, in turn, augments targets gene expression), while extrinsic noise broadens the oscillation frequency that can entrain cells, thereby increasing the chance of entrainment within the cell population. (Reprinted with permission from Kellogg, R.A., Tay, S., 2015. Noise facilitates transcriptional control under dynamic inputs. *Cell* 160, 381–392. © 2015 Elsevier.)

(Tay *et al.*, 2010) showed that intrinsic noise broadens the range of input periods that lead to and sustain NF- κ B oscillations required for entrainment, while extrinsic noise increases the chance that a subset of cells would entrain to a given dynamic input (analogous to bacterial bet-hedging (Veening *et al.*, 2008)). As a result, the combination of intrinsic and extrinsic noise enables output (i.e., nuclear NF- κ B oscillation) entrainment, which, in turn, leads to strong transcription of target genes in response to a range of dynamic inputs (Figure 4(c)). In the earlier study describing the hybrid model, the same high-throughput microfluidic device was used to reveal the digital nature of NF- κ B activation upon constant (non-oscillating) inputs at the single-cell level, with fewer cells digitally activated at lower input dose. Despite the digital nature of the response, some features such as maximum nuclear NF- κ B amount, response time to input and number of NF- κ B oscillations depended on input dose and thus were analogue (Tay *et al.*, 2010).

Cellular Structures Controlling T Cell Signaling in Time and Space

Introduction

T cells activate in a cellular interaction with antigen presenting cells (APC). The central activating receptor is the T cell receptor (TCR) that recognizes antigenic peptides presented by major histocompatibility complex (MHC) molecules on the surface of the APC (Davis *et al.*, 2003). A substantial number of costimulatory receptors regulate the efficiency and functional outcomes of T cell activation. The ligands for most of these receptors are also expressed on the APC surface (Davis *et al.*, 2003). A large number of ligand-engaged receptors thus initiate T cell signaling at the cellular interface between a T cell and an APC in a polarized fashion. This triggers the activation of an even larger number of associated signaling intermediates. Understanding the functional integration of such complex signaling is an important unresolved challenge that is common among multiple cell types. Critical data to address this challenge are provided by the polarized nature of the subcellular organization of T cell signaling: During T cell activation, receptors and signaling intermediates are not necessarily evenly distributed within the T cell but can enrich at particular regions at specific times, creating complex spatiotemporal signaling distributions. The resulting highly structured interface between the T cell and the APC is often referred to as an 'immunological synapse'. As co-enrichment of signaling intermediates enhances the efficiency of their interaction, uneven spatiotemporal signaling distributions control the flow of information through a signaling network and thus govern the efficiency of cellular activation. Understanding signaling organization thus provides unique insight into the function of complex signaling systems. While uneven signaling distributions are widespread in the activation of many cell types, a wealth of genetic, biochemical, and cell biological data makes T cell activation particularly well-suited to understand how subcellular signaling distributions are controlled and how they regulate cellular activation. Here we discuss approaches to study the organization of T cell signaling, principal structures driving it as the focus of this article, and difficulties in the determination of the functional significance of uneven subcellular signaling distributions that have limited its analysis to date.

Studying the Organization of T Cell Signaling

Approaches to Activate T Cells

T cell signaling plays a variety of roles in the *in vivo* life cycle of a T cell. T cells develop in the thymus in response to modest strength engagement of the TCR resulting in various distinct subsets, prominently CD4 helper and CD8 cytotoxic T cells. To ensure a diverse recognition repertoire, virtually every T cell expresses a different TCR. Upon completion of the thymic

development a 'naïve' T cell is highly motile, but remains largely quiescent from a cell cycle standpoint until it is triggered by strong engagement of its TCR. Naïve T cell activation triggers extensive functional differentiation, for example, into various helper subsets. Activated or 'primed' T cells execute effector functions within secondary lymphoid organs or at sites of infection in response to reengagement of their TCRs. The vast majority of activated T cells die within about a week with few T cells surviving as memory T cells. Throughout their life T cells interact with a variety of different cell types as APCs, for example, with the thymic epithelium during development, with dendritic cells during naïve T cell activation, or with B cells in support of their differentiation. This complex life cycle sets up a bewildering variety of scenarios to study T cell activation and the specific signaling organization associated with it. Here we will focus on the activation of primed CD4 T cells as the most widely studied experimental model.

As practically every T cell expresses a different TCR, a population of *in* or *ex vivo* T cells cannot be activated through engagement of their TCRs by a single MHC peptide complex. There are various approaches to circumvent this problem. Mice can be genetically engineered to have all of their T cells express the same TCR with a defined MHC/peptide recognition specificity. Much of the work reviewed here uses this approach. Human T cells with a given recognition specificity can be maintained through periodic restimulation with their cognate antigen *in vitro* or they can be immortalized. Alternatively, antibodies or superantigens can be used to activate T cells irrespective of their TCR recognition specificity, as commonly used to study human T cells. Different activation regimes can be executed in the context of different APCs, B cells are widely used, or by employing reductionist approaches as introduced in the following paragraph. Given the large number of different scenarios and methods to activate a T cell, it is of utmost importance to keep in mind that the experimental constraints of the particular approach of T cell activation chosen differentially shape T cell signaling and its subcellular organization (Brossard *et al.*, 2005; Schubert *et al.*, 2012; Richie *et al.*, 2002; Ebert *et al.*, 2008; Hailman *et al.*, 2002; Zanin-Zhorov *et al.*, 2010).

Methods to Study T Cell Organization

Physiological activation of T cells occurs in the cellular interaction of T cells with various types of APCs in secondary lymphoid organs or at a site of infection. Signaling organization thus should ideally be studied in this context. Two-photon microscopy has been incredibly successful in tracking the motion of immune cells inside intact organs (Okada *et al.*, 2005; Mempel *et al.*, 2004; Bajenoff *et al.*, 2006; Celli *et al.*, 2005; Witt *et al.*, 2005; Skokos *et al.*, 2007). However, technical constraints, in particular difficulties in distinguishing productive from accidental T cell:APC contacts and in

delineating T cell:APC interfaces as the site of signaling initiation, have made it very difficult to study subcellular signaling organization *in vivo*. With the exception of a few pioneering studies (Azar *et al.*, 2010; McGavern *et al.*, 2002; Melichar *et al.*, 2013), most of the work on the organization of T cell signaling has therefore been performed *in vitro*, the focus of this article. Supporting the utility of *in vitro* studies, cell coupling inside secondary lymphoid organs shows comparable dynamics and responses to varying T cell stimuli (Henrickson *et al.*, 2008; Zheng *et al.*, 2008; Azar *et al.*, 2010; Moreau *et al.*, 2012; Henrickson *et al.*, 2013) as cell coupling *in vitro*.

T cells are a difficult cell type to address with cell biological means, as T cells are non-adherent motile small cells (7–9 μm diameter) with most of the T cell volume taken up by the nucleus. As they are activated in a cellular interaction, only the subset of T cells in tight cell couples with APCs yields relevant data. T cell:APC couples can be observed by live cell imaging using, for example, spinning disk confocal microscopy. This requires the rapid acquisition of three-dimensional volumes, limiting resolution. Therefore, from its beginning T cell organization has also been studied in reductionist systems, where the APC is substituted by a flat surface, either supported lipid bilayers (SLB) or antibody-coated cover slips (Grakoui *et al.*, 1999). This allows precise control of the T cell stimulus and access to single z-plane high-resolution imaging, for example, in tracking diffraction-limited objects by total internal reflection fluorescence microscopy or by applying recent superresolution approaches. Glass cover slips can be coated with ligands for receptors on the T cell surface, commonly antibodies against the TCR. In this setting the location of receptor engagement is fixed as antibodies cannot move on the glass surface and signaling organization is determined in relation to this localized receptor engagement. Alternatively, ligands for receptors on the T cell surface can be inserted into SLB generated by spreading small unilamellar vesicles on glass. In this setting the ligands remain mobile, allowing for receptor:ligand transport at the interface between the T cell and the SLB, similar to a T cell:APC interface. However in contrast to a T cell:APC interface, the SLB cannot be deformed to allow for extensive membrane undulations and internalization of receptor:ligand couples into the T cell. Finally, only electron microscopy can resolve T cell organization at the scale of a few nm, as for example, required in analyzing membrane topology at the plasma membrane and in vesicles. However, this requires extensive sample processing.

The fundamental role of signaling organization is to regulate when and where signaling intermediates interact with each other. The more signaling intermediates are studied in the same experimental system the more signaling interactions can be addressed. Systems biology approaches thus are particularly powerful in understanding signaling organization. Initial studies with more than ten signaling intermediates analyzed with the same T cell:APC combination have revealed a remarkably diverse organization of T cell signaling in time and space and substantial sensitivity to alterations in T cell stimuli (Singleton *et al.*, 2011, 2009), establishing that T cell signaling organization can be highly information rich.

In summary, with the large variety of approaches to activate and image T cells, each individual study can only hope to capture a small part of signaling organization and its function.

Technical constraints of a particular approach used need to be kept in mind and every attempt should be made to integrate as much of the available data as possible under consideration of these constraints to slowly approach the scope of system insight required to understand something as complex as T cell signaling organization and its function.

Signaling Organization and the Structures Driving It

Signaling organization is governed by a large set of elements of cellular architecture that cross-regulate each other in a complex fashion. Critical elements include membrane topology, cytoskeletal structures, and complexes of receptors and/or signaling intermediates. Membrane topology at the cellular interface and through vesicular trafficking, determines how many receptors can engage their ligands at which location. Cytoskeletal structures control membrane topology and can constrain and move receptors and signaling intermediates. Receptor complexes control the efficiency of signaling initiation. Together with membrane topology and cytoskeletal structures they shape signaling distributions. Signaling complexes can stabilize such distributions and the resulting localization of signaling intermediates feeds back on the structures driving it, in particular through local control of cytoskeletal dynamics and vesicular trafficking. Individual elements of signaling organization thus cannot be comprehensively understood in isolation. Figure 1 presents all elements of cellular architecture discussed in context.

T Cell Shape and Plasma Membrane Topology

In general, the dynamics of cell coupling, for example, the duration of cell couples, the frequency of their often sequential formation, or the number of cells bound simultaneously, constrain T cell signal initiation and transduction, an important question that is beyond the scope of this article and addressed elsewhere (Davis, 2009; Batista and Dustin, 2013). At the level of individual cell couples as discussed here, the topology of the cellular interface between a T cell and an APC constitutes a primary determinant of the initiation of signaling through receptor engagement.

Even prior to binding to an APC, a T cell is polarized. Two defining elements of T cell polarity are an actin-rich leading edge and a posterior extension with the microtubule organizing center (MTOC) at its base, the uropod. Some receptors and signaling intermediates are enriched in the uropod, such as ICAM-2, ezrin, and moesin (Yonemura *et al.*, 1998; Savage *et al.*, 2002). A network of PDZ-containing proteins plays an important role in such polarization (Ludford-Menting *et al.*, 2005). Upon formation of a tight cell couple some receptors including the TCR are partially and transiently recruited to the uropod before being released to the interface when the uropod is retracted as a consequence of T cell activation (Singleton *et al.*, 2009). Other receptor and signaling intermediates are moved to or remain behind the nucleus in a tight cell couple, forming the distal pole complex, as reviewed elsewhere (Cullinan *et al.*, 2002). Nevertheless, upon formation of a tight cell couple, most receptors move to the T cell:APC interface (Singleton *et al.*, 2009).

Dynamic cellular structures that regulate the spatiotemporal organization of T cell signaling and activation

Figure 1 The figure summarizes the cellular structures that control the organization of T cell signaling in T cell:APC couples. The T cell is indicated in light brown, the APC in gray. In the three panels from top to bottom different structures are highlighted as indicated and panels on the right zoom into the cellular interface. As T cell cellular structures are dynamically regulated, two zoomed-in panels are shown, one representing early T cell activation, i.e., within the first 5 min of tight cell coupling at the peak of biochemical signaling activity, and the other representing late T cell activation thereafter. Receptors are indicated in blue, their ligands in turquoise, actin in light grey, microtubules in dark brown, and signaling intermediates in pink. Thick black arrows indicate direction of actin protrusion and retrograde transport.

In a T cell:APC couple the cellular interface contains numerous smaller and larger undulations, with T cell protrusions reaching into APCs and APC membrane being pulled into the T cell (Ueda *et al.*, 2011; Singleton *et al.*, 2006; Sage *et al.*, 2012). The cumulative effect of these undulations can increase the area of T cell membrane at the T cell:APC interface to up to 4-fold over the area that a completely flat interface would occupy. Membrane undulations thus dramatically enhance the area available to receptor:ligand engagement. The extent of these membrane undulations is dynamically regulated. The undulations are most dramatic within the first couple of minutes of tight T cell:APC interface formation (Roybal *et al.*, 2013) when biochemical signaling activity peaks but are sustained somewhat less prominently over hours (Ueda *et al.*, 2011). At least the early burst in membrane undulations is likely driven by actin dynamics, when numerous small actin structures are aligned perpendicular to the cellular interface, possibly driving it outward. Directly linking membrane topology to signaling organization, the TCR can enrich in small membrane protrusions (Sage *et al.*, 2012). A distinct element of membrane undulations is a large T cell invagination that forms selectively within the first couple of minutes of tight cell coupling at the center of the T cell:APC interface and that can reach several μm deep into the T cell with APC membrane still attached (Singleton *et al.*, 2006). Signaling intermediates, for example, active Rho, and receptors such as CD2 or even the TCR are enriched at the base of the transient invagination (Singleton *et al.*, 2006, 2011). However, their subsequent fate is unresolved and the suggested function of the invagination in resetting early T cell signaling needs to be corroborated.

The distance between the T cell and APC plasma membranes at the even smaller scale of tens of nm is critical for receptor function and localization. Experimental and theoretical studies show that receptor ligand confinement at a cellular interface shapes the affinity of receptor ligand binding, likely as a function of the membrane distance (Huppa *et al.*, 2010; Hu *et al.*, 2013; Dustin *et al.*, 1996). In addition, it has long been suggested that the distance between the T cell and the APC membrane is critical for sorting receptor:ligand couples into distinct areas by size. Strong support for this notion comes from experiments where changing the dimensions of receptors on the T cell surface dramatically impacts their function (Wild *et al.*, 1999; Choudhuri *et al.*, 2005). In addition, receptors with a particularly large extracellular domain, prominently CD43 and the phosphatases CD45 and CD148 tend to be removed from the cellular interface upon cell coupling (Lin and Weiss, 2003; Leupin *et al.*, 2000; Allenspach *et al.*, 2001; Delon *et al.*, 2001; Roumier *et al.*, 2001; Johnson *et al.*, 2000) or from the vicinity of ligand-engaged TCRs when analyzed in T cells activated on SLBs (Varma *et al.*, 2006), consistent with a size-based sorting mechanism.

The function of the different forms of membrane undulations is uncertain, as it is virtually impossible to establish causality by changing T cell membrane topology experimentally without affecting various other elements of cellular architecture and signaling. Nevertheless, from biophysical first principles these structures should shape T cell signaling to a substantial extent. For example, altered membrane curvature and the dramatically increased membrane surface to

cytoplasm volume ratio in T cell membrane protrusions should alter signal progression (Meyers *et al.*, 2006; Neves *et al.*, 2008; Rangamani *et al.*, 2013; Schmick and Bastiaens, 2014). Plasma membrane undulations as highly deformed membrane structures should affect molecular interactions at the membrane, as for example, Bin/Amphiphysin/Rvs (BAR) proteins bind to and maintain curved membrane structures providing a link to various actin regulators (Antonny, 2011).

Vesicle Trafficking

Continuously, secretory and recycling vesicles fuse with the plasma membrane and endocytic vesicles internalize at the plasma membrane, controlling the area, and composition of the plasma membrane. In addition, exocytic vesicles can bud from the plasma membrane. The number of receptors accessible to ligand at the T cell:APC interface thus can be carefully controlled. As a prominent example, even prior to APC contact the TCR continuously cycles through the endocytic pathway. Upon T cell activation, a substantial decrease in TCR plasma membrane expression is mediated through lysosomal rerouting of the TCR in endosomes (Liu *et al.*, 2000; Das *et al.*, 2004; Finetti *et al.*, 2009). In addition, vesicles containing TCRs are secreted in an ESCRT-dependent fashion by the T cell at the center of the T cell:APC interface, again preventing the TCRs from participation in signal transduction (Choudhuri *et al.*, 2014). Inversely to vesicular TCR trafficking, the critical inhibitory receptors CTLA-4 and Lag-3 are largely contained in vesicles inside the T cell and only become inserted into the plasma membrane upon the activation of a naïve T cell (Woo *et al.*, 2010; Jansson *et al.*, 2005; Linsley *et al.*, 1996). The control of interface localization through vesicular trafficking also extends to signaling intermediates, in particular receptor proximal signaling intermediates that are membrane associated and their interaction partners. As prominent examples, the tyrosine kinase Lck that phosphorylates the TCR and the adaptor proteins Linker of activated T cells (LAT) and SLP-76 that constitutes the principal signaling platforms immediately downstream of the TCR are inserted into the plasma membrane from vesicles in distinctly regulated fashions and are internalized as a consequence of TCR engagement (Soares *et al.*, 2013; Anton *et al.*, 2011; Barr *et al.*, 2006). Interestingly, internalized TCR can remain active as long as it remains associated with Lck (Yudushkin and Vale, 2010) even though it is unresolved, whether the MHC/peptide ligand or membrane patches from the APC surface containing it can be pulled out of the APC surface to provide continued TCR engagement in the endocytic vesicles. The question of how much of LAT activity during T cell activation is provided by the plasma membrane pool of LAT versus LAT coming from secretory and recycling vesicles is discussed controversially (Purbhoo *et al.*, 2010; Williamson *et al.*, 2011; Balagopalan *et al.*, 2013). Again, it is exceedingly difficult to generate causal experimental support for functional relevance of specific trafficking events. Nevertheless corroborating the principal importance of vesicular trafficking, interference with the function of general regulators of vesicle fusion and trafficking has consistently shown that vesicular trafficking shapes T cell signaling to a substantial extent (Larghi *et al.*, 2013; Vardhana *et al.*, 2010; Gomez *et al.*, 2005).

Cytoskeletal Dynamics

For more than two decades it is well established that the T cell cytoskeleton with its two principal components, the microtubule network originating at the MTOC and the actin network, repolarizes upon formation of a T cell:APC couple (Kupfer and Singer, 1989). In a migrating T cell prior to cell coupling the MTOC is located behind the nucleus at the base of the uropod. Upon cell couple formation the MTOC swings around the nucleus within a few minutes to become positioned right behind the center of the T cell:APC interface (Tskvitaria-Fuller *et al.*, 2003; Kuhn and Poenie, 2002). MTOC reorientation is driven by TCR signaling (Lowin-Kropf *et al.*, 1998; Quann *et al.*, 2011). The mechanism of MTOC reorientation is still being debated. Suggested mechanisms include attachment of microtubule ends in a ring around the interface periphery with centripetal pulling to center it (Kuhn and Poenie, 2002) and attachment of microtubule ends at the interface center with capture-shrinkage to position the MTOC (Yi *et al.*, 2013). MTOC localization is important for signaling organization as the vast majority of the T cell vesicular machinery moves with the MTOC (Quintana *et al.*, 2007).

Actin dynamics extensively shape signaling organization by direct and indirect means: They control cell shape, membrane topology, and short-distance vesicle trafficking, signaling intermediates can position themselves through direct actin binding and can be transported by actin motion, and dense actin matrices can trap signaling complexes. Actin dynamics are therefore likely the most studied element of signaling organization in T cell activation. There are four principal T cell actin structures. Within seconds of the initiation of T cell coupling, be it to an APC or a planar substitute thereof, actin forms a peripheral ring that pushes the edge of the interface outward in the formation of a tight cell couple (Bunnell *et al.*, 2001; Tskvitaria-Fuller *et al.*, 2003). In T cell:APC couples the peripheral actin ring is prominent only for a few minutes, in T cell activation on planar APC substitutes it last considerably longer. In T cell:APC couples the peripheral actin ring can be accompanied by an equally transient second structure, a dense actin matrix that reaches from the undulating cellular interface deep into the T cell across the entire interface (Roybal *et al.*, 2013). A similar matrix is seen in the coupling of natural killer cells to their targets (Rak *et al.*, 2011; Brown *et al.*, 2011). During the entire duration of cell coupling, the cortical actin network underlying the T cell plasma membrane similar to other cell types enriches at the cellular interface. Finally, after a few minutes of cell coupling, actin often enriches in individual lamellar extensions that can occur at the edge of the interface to maintain it or away from the interface when a T cell repolarizes to another APC.

Actin is highly dynamic. The use of planar APC substitutes has been instrumental in providing access to F-actin motion. When T cells are activated on planar APC substitutes, actin moves from the peripheral actin ring inward, possibly with decreasing velocity as it approaches the interface center (Yi *et al.*, 2012; Babich *et al.*, 2012). This actin motion provides a centripetal transport machinery for the organization of T cell signaling (Babich *et al.*, 2012; Yi *et al.*, 2012). The role of the motor protein Myosin II in this actin motion is still being debated (Hammer and Burkhardt, 2013). It needs to be

established how this centripetal actin motion is oriented in a T cell:APC couple, where in particular early during cell coupling large membrane undulations impair the formation of a continuous actin network in the interface plane, rather breaking actin up into discreet structures aligned with the undulations (Figure 1). Actin dynamics are controlled by TCR signaling in conjunction with costimulation (Tskvitaria-Fuller *et al.*, 2003; Wülfing and Davis, 1998). Some interface actin enrichment accompanies T cell coupling in response to virtually every stimulus. However, the extent and dynamics of actin turnover are likely used by the T cells as a critical means to tune to efficiency of T cell signaling (Roybal *et al.*, 2013). Illustrating the general importance of actin dynamics for T cell activation, genetic deletion of virtually every protein that controls actin turnover, for example, WAVE2, the hematopoietic cortactin homolog HS1, Cofilin, or Coronin, leads to substantial defects in signaling organization and cellular function (Billadeau *et al.*, 2007; Gomez *et al.*, 2006; Nolz *et al.*, 2006; Badour *et al.*, 2003; Snapper *et al.*, 1998; Cannon and Burkhardt, 2004; Cannon *et al.*, 2001; Labno *et al.*, 2003; Zipfel *et al.*, 2006; Foger *et al.*, 2006; Mugnier *et al.*, 2008; Eibert *et al.*, 2004). However, again it is technically exceedingly difficult to causally link distinct actin structures to signaling organization and the regulation of T cell activation.

Signaling Complexes – The Central Supramolecular Activation Cluster

Already in the first studies characterizing T cell signaling organization, accumulation of receptors, for example, ligand-engaged TCR, and signaling intermediates, for example, protein kinase C (PKC) Θ , at the center of the T cell:APC interface was described (Monks *et al.*, 1998, 1997; Grakoui *et al.*, 1999). Kupfer termed such accumulation the central supramolecular activation complex or central supramolecular activation cluster (cSMAC). Work using planar APC substitutes has established that ligand-engaged receptors move centripetally in the T cell:APC interface to enrich in the cSMAC (Varma *et al.*, 2006; Yokosuka *et al.*, 2005; Kaizuka *et al.*, 2007). The velocity of this receptor transport is similar to that of the centripetal actin motion, suggesting that actin drives receptor transport. Proteins in the cSMAC, be it in T cells activated with APCs or on SLB, display dramatically reduced mobility, consistent with the idea that the cSMAC is a highly cross-linked protein complex with potentially distinct physical phase properties (Rocha-Perugini *et al.*, 2013; Li *et al.*, 2012). The importance of the cSMAC for T cell activation has long been controversial. A large number of receptors and signaling intermediates accumulate at the interface center when T cells receive a strong stimulus (Singleton *et al.*, 2009). However, efficient T cell activation can occur in the absence of cSMAC formation and in response to weaker stimuli receptor clustering in the cSMAC is commonly lost even though accumulation of PKC Θ is retained (Singleton *et al.*, 2009; Purdie *et al.*, 2005; Lee *et al.*, 2002; Purbhoo *et al.*, 2004). Curiously the accumulation of active signaling intermediates in the cSMAC is less prominent than that of ligand-engaged receptors (Singleton *et al.*, 2009). This is particularly pronounced in T cells activated on SLB, where hardly any signaling activity resides in the cSMAC (Varma *et al.*, 2006). Based on these

observations, it seems likely that the mutual clustering of numerous receptors and signaling intermediates with high valence interaction motifs drives cSMAC formation as enhanced by centripetal actin transport. Turnover of receptors and signaling intermediates in the cSMAC as likely influenced by vesicular trafficking then determines how much signaling activity resides in the cSMAC. When the cSMAC can turnover efficiently to allow continuous exchange of molecules with the remainder of the T cell signaling system, it may enhance signaling by allowing signaling intermediates to dynamically concentrate, as possibly the case in T cell:APC couples. When the cSMAC becomes sufficiently immobile to prevent exchange with the remainder of the cell or when parts of it become separated from the cytoplasm through sorting into extracellular vesicles (Choudhuri *et al.*, 2014), the cSMAC may impair signaling by sequestering receptors and signaling intermediates, as possibly the case in T cell activation on planar surfaces. The sorting of TCR into extracellular microvesicles spares engaged CD28, which continues to signal through PKC- θ . Independent of the amount of signaling provided by the cSMAC, a substantial part of T cell signaling occurs outside the cSMAC in smaller receptor and signaling intermediate assemblies.

Signaling Complexes – Microclusters

The use of planar surfaces as APC substitutes has been instrumental in identifying smaller receptor and signaling clusters. Even prior to T cell activation in naïve and even more so primed T cells, TCRs are localized in clusters of dozens of molecules (Boyle *et al.*, 2011; Fahmy *et al.*, 2001; Kumar *et al.*, 2011). Upon T cell activation on SLB it can be readily observed that such clusters grow to up to hundreds of molecules, giving rise to ‘microclusters’ (Yokosuka *et al.*, 2005; Varma *et al.*, 2006). A single agonist peptide/MHC complex is sufficient to drive the clustering of hundreds of TCRs (Huang *et al.*, 2013). Microclusters form at the periphery of the interface and upon initial TCR signaling associate with a substantial part of known proximal signaling intermediates, starting with ZAP-70, the adaptor proteins LAT and SLP-76 all the way to Nck and WASP (Bunnell *et al.*, 2002; Barda-Saad *et al.*, 2005). Ligand-engaged TCRs then move toward the interface center in an actin-dependent process (Xie *et al.*, 2012). Microclusters need to have a minimal size to be transported centripetally (Hartman *et al.*, 2009). During transport, more distal signaling intermediates dissociate from the microclusters over time, SLP-76 to move to a perinuclear structure, Nck and WASP to move into the actin-rich region at the periphery of the interface between the T cell and the planar surface (Bunnell *et al.*, 2002; Barda-Saad *et al.*, 2005). Upon reaching the cSMAC, much of the remaining associated signaling activity is lost (Varma *et al.*, 2006). When T cell activation is disrupted either by blocking TCR engagement or actin dynamics, receptor clustering in the microclusters rapidly dissolves, suggesting that microclusters are dynamically maintained (Varma *et al.*, 2006). Super-resolution and electron microscopy have provided further detail in the characterization of signaling clusters. Prior to T cell activation, clusters of T cell surface molecules, including the TCR, LAT and lipid markers were found to be mostly separate. Upon TCR engagement, clusters grow in size and become adjacent to each other, but only partially mix

(Sherman *et al.*, 2011; Lillemeier *et al.*, 2006, 2010). Similar spatial separation at the nm scale of ligand-engaged receptors and LAT is found in mast cell activation (Wilson *et al.*, 2001).

Together, the work using planar APC substitutes strongly suggests that the control of the clustering of receptors and signaling intermediates, overlapping but also with clear spatial distinctions, in combination with actin-dependent transport of signaling clusters plays a major role in shaping the organization of T cell signaling. It remains to be seen, how the more undulating plasma membrane topology in T cell:APC couples with its increased membrane flexibility and more local actin structures shape the formation and transport of signaling cluster at the T cell:APC interface. Curiously, the spatial segregation of proximal and distal signaling observed in T cells activated on planar APC substitutes is substantially more pronounced in T cell:APC couples (Roybal *et al.*, 2013). Moreover, it remains unresolved how much signaling activity is mediated by even smaller groups or individual receptors outside the microclusters with some such signaling activity likely (Schamel *et al.*, 2005).

Summary of Signaling Structures

A large number of structures govern signaling organization in T cell activation, membrane topology, vesicular trafficking, actin dynamics, and large and smaller protein complexes. Importantly, the extent to which these structures form varies depending on how the T cell is activated. Moreover, the mapping of signaling intermediates onto these structures is to date only been executed in a highly fragmented fashion, with generally only few signaling intermediates mapped to few structures in different experimental systems. As a field we are thus still far away from comprehensively understanding how T cell signaling is organized in time and space. Nevertheless, the remarkable extent of the control of the localization of receptors and signaling intermediates inside a T cell discussed here makes it is safe to assume that the organization of signaling is a principal regulator of T cell function.

Signaling Organization Varies with T Cell Activation Conditions

Even while a comprehensive picture of the organization of T cell signaling is still lacking, individual smaller data sets already strongly suggest that signaling organization is highly sensitive to T cell activation conditions. As an illustration, a few almost random examples are listed here. In T cell maturation thymocytes undergoing positive and negative selection display hardly any or distinctly less patterning (Richie *et al.*, 2002; Ebert *et al.*, 2008). In T cell differentiation Th2-polarized T cells show less central TCR patterning and lipid raft accumulation than Th0 or Th1 cells (Balamuth *et al.*, 2001; Singleton *et al.*, 2011). Regulatory T cells have PKC θ shifted from the T cell:APC interface to the distal pole (Zanin-Zhorov *et al.*, 2010) and recruitment of a large GIT/Pix complex to CTLA-4 is restricted to regulatory T cells (Kong *et al.*, 2014). T cells expressing a self-reactive TCRs yield less pronounced spatiotemporal organization upon activation than those expressing a TCR recognizing foreign antigens (Schubert *et al.*, 2012). Engagement of the

TCR with a lower affinity peptide widely impairs accumulation at the interface center (Monks *et al.*, 1998; Singleton *et al.*, 2009). While these examples provide an idea of the impressive variability of signaling organization, much work needs to be done to move from these individual observations to a more comprehensive understanding of how T cell activation conditions govern signaling organization.

The Function of Signaling Organization

By controlling when and where signaling interactions can efficiently proceed, signaling organization should be of fundamental importance in determining, how the activity of dozens of receptor and signaling intermediates is integrated in a signaling network. This should be critical in tuning cellular activation, in T cells for example in the adjustment of T cell reactivity in the distinction between protection of our own body versus effective attack on cancer cells and infectious agents. However the comprehensive verification of this prediction of the functional importance of signaling organization is still lacking, as signaling organization is uniquely difficult to study in an unambiguous causal fashion. When one wants to understand the function of a particular protein, knockout mice, RNAi or overexpression provide straightforward approaches for causal manipulation. However, required for a definite assessment of the importance of a particular signaling structure are experiments where this structure is changed while others are not directly targeted and while the activity of signaling intermediates is not directly affected. Such experimental regimens are exceedingly difficult to generate, let alone in a consistent fashion. Therefore signaling organization has to be studied slightly differently. When a structure cannot be interfered with specifically, then it should be carefully characterized what happens to other structures in any chosen interference regimen. For example, to assess the importance of the peripheral actin ring, it should be evaluated what the effect of a drug that effectively blocks peripheral actin ring formation is on other actin structures, such as cortical or lamellar actin. Thus it can be established that the intended structure is indeed the major target of the drug treatment and in retrospect, consequences of the drug treatment could be linked to its smaller effects on other structures if prompted by emerging data. In addition, multiple such studies are likely needed to understand the importance of a single structure: Only when the loss of a structure is consistently associated with the same outcome, some certainty is gained about its function. This can be accomplished within a single study, where multiple interference regimes are tested or it can happen across multiple studies from different laboratories. A good example for the integrative effect of multiple studies is the investigation of the importance of the cSMAC, where initial studies (Monks *et al.*, 1997; Lee *et al.*, 2003, 2002; Stinchcombe *et al.*, 2001) reached widely divergent conclusions, that the cSMAC is required for signaling, not required for signaling, required for directed vesicular secretion. Only over many years a more comprehensive picture, as discussed above, has emerged. Across the field the function of T cell signaling organization and the various cellular structures associated with it thus remains widely uncertain. Because of the fragmented and incomplete

knowledge of the function of signaling organization, a comprehensive review of the data addressing the functional significance of the different elements of subcellular architecture discussed here is well beyond the scope of this manuscript. However, many methods and data addressing T cell organization have been discussed in two entire recent journal volumes of reviews dedicated to the cell coupling and the cytoskeleton (Burkhardt, 2013; Batista and Dustin, 2013).

Glossary

Apical region The side of a cell that faces either the external environment or the lumen.

Basolateral region The side of a cell in contact with the underlying tissue.

Epithelium Animal tissue comprised of a network of cells that line the cavities and surfaces of an animal.

Lumen Interior side of a tubular structure.

Microvilli A membrane protrusion on the apical surface of an epithelial cell that increases surface area.

Simple epithelium Epithelium consisting of a single layer of cells found where secretion and absorption occur.

Stratified epithelium Epithelium consisting of two or more layers of cells found where abrasion may occur.

Introduction

Compartmentalization is a fundamental feature of life. One of the first lessons of biology is that we are an aggregate of cells with lipid bilayer membranes, and that these cells themselves contain membrane-bound compartments termed organelles. In animals, compartmentalization at the whole organism level is achieved by the epithelium, which refers to the network of cells that line the cavities and surfaces of our body. In addition to the skin that serves as the boundary between our internal environment and the outside world, an epithelial layer lines the digestive tract, lungs, kidneys, urinary tract, and other organs to maintain separation of their contents. However, the function of the epithelium is not limited to that of a static physical barrier. Like the membranes that surround cells and organelles, the epithelium mediates the exchange of chemicals and other materials between the internal and external environment. Epithelia are also responsible for sensing the external environment as well as serving as a primary defense mechanism. Consequently, the cells that make up the epithelium are as diverse in their appearance and function as the organs in which they are found.

This article will present an overview of the variety and function of epithelia, and use examples to illustrate the dynamic nature of this major type of animal tissue. In the first section, we will discuss structural features of the epithelium. The second section will examine how individual epithelial cells reflect the specialized function of this tissue and the associated organs. Many features of the epithelium reflect the tremendous evolutionary pressure conferred by infectious disease. Therefore, in the third section we will use the role of epithelia in immunity to highlight the complexity of barriers. Finally, we will discuss the epithelium in the context of disease and discuss the recent advances in research in this area. The endothelium, the layer of cells that line the inside of blood and lymphatic vessels, is frequently included in discussion of the epithelium and also serves as a barrier. Although many of the same principles apply, the endothelium has its own unique properties and will not be discussed further. In many parts of this article, we will use the intestinal epithelium as an example. Many of the recent advances in epithelial biology highlight the extraordinary mechanisms utilized by the intestinal epithelium to maintain coexistence with the vast amount of bacteria present in close proximity. By discussing the key

cell biological features of epithelia, we hope that the reader will appreciate that the epithelial barrier is every bit as dynamic as the underlying organs and cavities they surround.

Structure of the Epithelial Layer

Epithelia are derived from all three primary germ layers, and cells derived from each layer establish distinct compartments. For example, the external skin is derived from the ectoderm, while the endoderm forms the linings of the gastrointestinal and respiratory tracts, and the mesoderm gives rise to renal epithelium. The structure of the epithelium reflects their location and function. The gastrointestinal tract, lungs, and kidneys are lined with a simple epithelia, which consists of a single layer of cells, while the outer epithelium, the skin, is a stratified epithelium that is several layers thick (Alberts *et al.*, 2008). Simple epithelia are found where secretion and absorption or passive diffusion occur, and frequently have cilia or microvilli, a membrane protrusion that increases surface area. In contrast, stratified epithelium are thicker, consisting of two or more layers of cells, and usually have a protective role.

The simple and stratified epithelium can be further divided into squamous, cuboidal, and columnar based on the shape of the cells that comprise the layer (Bryant and Mostov, 2008). Squamous epithelial cells are flattened cells with irregular scale-like shapes. Simple squamous epithelia are found lining the cavities of the body including the pericardial, pleural, and peritoneal cavities, or in areas where passive diffusion occurs, such as glomeruli in the kidney and alveoli in the respiratory tract. Stratified squamous epithelium is comprised of several layers of epithelial cells, the bottom of which is in contact with a basement membrane that underlies the epithelium. Above this layer are additional layers of cells of different shapes and number, with the top layer being a flattened squamous layer of epithelium. This type of epithelium is found in areas of the body subject to frequent abrasion, as underlying tissues can remain protected even when the surface layer of cells is lost, and are found lining the anal canal, cervix and vagina, pharynx, and esophagus. As their names imply, cuboidal epithelial cells are roughly shaped like cubes, and columnar epithelial cells are taller than wider. Simple cuboidal epithelial cells are located in the ovaries and parts of the kidney including nephrons and renal tubules. Stratified cuboidal epithelial cells are less common and are found lining salivary, mammary, and sweat glands. Large portions of the gastrointestinal tract are lined with simple columnar epithelia. While comprised of only a single layer of cells, parts of the upper respiratory tract are lined with pseudostratified epithelium, which at first glance appears to have more than one layer due to an uneven positioning of nuclei in neighboring cells. Stratified columnar epithelia are less common and found in reproductive organs such as the uterus and vas deferens, as well as parts of the gastrointestinal tract like the pharynx and anus.

These structural differences reflect the local environment and organ function. The protective barrier provided by the stratified epithelium of the skin is essential for preventing contamination of the underlying tissue from noxious chemical and infectious material present in the external environment

(Tsukita and Furuse, 2002). In stark contrast to the multi-layered epithelium of the skin, the single layer of cells of the alveoli allows for exchange of carbon dioxide and oxygen by diffusion (Hasenberg *et al.*, 2013). The simple epithelium of the renal tubule both forms a barrier between the renal interstitium and the sterile tubular interior (lumen), and maintains a gradient that allows for regulated nutrient and water transport and urine production (Field *et al.*, 1989). The structural integrity of these diverse epithelia relies on the polarization of the individual cells. Epithelial cells have an apical region, which faces either the lumen or the external environment in the case of the skin, and a basolateral region in contact with the underlying tissue (Bryant and Mostov, 2008). The tight junction (discussed below) and everything above is considered the apical portion of the cell, and everything below is the basolateral portion (Baum and Georgiou, 2011). Lateral membranes, where the junctional complexes are located, exist between neighboring epithelial cells. The apical and basolateral surfaces of epithelial cells have different features, such as microvilli on the apical surface of many epithelial cells. Also, the distribution of proteins, intracellular organelles, and cytoskeletal components can differ significantly between the two regions (Bryant and Mostov, 2008). Polarity is achieved with assistance from the cytoskeleton, which serves as a structural framework for shape and supports membrane traffic. Rather than creating an inflexible structure, the cytoskeleton allows dramatic remodeling when necessary. For example, contraction of the actomyosin circumferential belt has been shown to be a mechanism by which apoptotic cells in the intestinal epithelium are extruded from the monolayer without compromising the barrier (Rosenblatt *et al.*, 2001).

The ability of epithelia to maintain polarity and create uninterrupted boundaries is made possible by the junctions between cells. While good for providing a strong barrier, impermeant junctions would not allow diffusion or transport across the epithelium. Thus a highly regulated, selectively permeable barrier exists in simple epithelia such as the one found in the intestine. Intercellular junctions seal the space between neighboring epithelial cells, preventing unregulated movement across the epithelium between cells (Turner, 2006). The three main junctional complexes between epithelial cells are the tight junction, the adherens junction, and desmosomes. The tight junction is the most apical of these complexes, and though it is the primary determinant of epithelial barrier function, it does not provide much strength to the intercellular bond (Pappenheimer and Reiss, 1987). Proteins that comprise the tight junction include transmembrane proteins such as occludin, marvelD3, and many claudin family members that interact with peripheral membrane proteins in the cytoplasm including ZO-1, -2, and -3 and link to the actin cytoskeleton (Mitic and Anderson, 1998). Tight junction proteins must maintain an intact barrier during physiological events including epithelial cell shedding, apoptosis, and pathophysiological events-like small injuries (Rosenblatt *et al.*, 2001; Bement *et al.*, 1993). Below the tight junction complex is the adherens junction. The adherens junctions do not contribute to the barrier function of the epithelium, but are instead a structural component of the junctional complex, providing strength needed to hold the neighboring epithelial cells together to form a continuous sheet (Baum and

Georgiou, 2011). Proteins of the adherens junction are predominately the E-cadherin adhesion molecules and the cytoplasmically associated catenins (Hermiston and Gordon, 1995). Catenins interact with F-actin and other components of the actin cytoskeleton to form and stabilize puncta. In addition to conferring strength, these junctions are important for epithelial cell differentiation and polarization. On the lateral membrane of the epithelial cells and basal to the adherens junction are the desmosomes, which connect to keratin intermediate filaments and provide further mechanical stabilization of the epithelial sheet (Turner, 2006). The transmembrane proteins that comprise the desmosomes are cell adhesion molecules, primarily from the cadherin family. The basal interaction of the epithelial cells with the basement membrane (an extracellular matrix sheet) is mediated by integrin family adhesion molecules that link to the actin and intermediate filament (hemidesmosomes) cytoskeletons. Together, these junctional complexes maintain a mechanically robust and chemically selective barrier.

Epithelial Cell Types

The individual cells that form epithelia are incredibly diverse in morphology and function. The epithelial cells of the gastrointestinal tract exemplify this diversity. The fundus of the stomach contains specialized epithelial cells that secrete hydrochloric acid and intrinsic factor, a glycoprotein necessary for absorption of vitamin B¹² (Schubert, 2011). The resulting acidic environment causes denaturation of ingested proteins, and together with chief cells that release enzymes, mediates proteolysis and ultimately absorption of nutrients. In the small intestine, finger-like projections called villi are covered by a monolayer of epithelial cells that maximize the surface area available for absorption (Bjerknes and Cheng, 2006). At the base of each villus is an invagination into the wall of the intestine, the crypt of Lieberkuhn. The epithelium of the colon does not contain villi, but is similar in that a monolayer of epithelial cells cover the crypts that emanate from the gut wall. Though the intestinal epithelium is made up of numerous cell types designed for different functions, these cell types have a common origin. Intestinal epithelial cells arise from Lgr5-expressing columnar stem cells located within the crypts (Barker *et al.*, 2007). Epithelial cells undergo three or four cell divisions and migrate away from the crypt base toward the villi in the small intestine or apical surface of the crypts in the colon. Cells that reach the tip of the villus or crypt are continuously shed during this process of renewal, resulting in turn over of the entire surface of the intestinal epithelium every 5–7 days (Bullen *et al.*, 2006).

Due to recent technical advances, signaling events that allow differentiation of functionally diverse intestinal epithelial cells are becoming clear. In addition to the stem cells, the base of the crypt is also home to Paneth cells, specialized cells of the small intestine which do not migrate up the villus but instead are longer lived residents of the crypts (Ouellette, 2010). Formation of Paneth cells relies on Wnt signaling, including the transcription factor Sox9 (Mori-Akiyama *et al.*, 2007). These secretory cells have two main functions, to provide growth factors important for maintaining neighboring

stem cells, and to aid in barrier maintenance and defense against bacteria in the intestinal lumen by secretion of antimicrobial factors (Ouellette, 2010). Another secretory cell important for maintaining homeostasis in the intestine is the goblet cell (Figure 1). These cells arise in the absence of Notch signaling, and rely on the transcription factors Spdef and Klf4 for their differentiation (Noah *et al.*, 2011; Katz *et al.*, 2002). Goblet cells are simple columnar epithelial cells found interspersed among other epithelial cell types in the gastrointestinal and respiratory tracts. Goblet cells secrete mucin, the main component of the mucus layer which coats the apical surface of the epithelium and provides protection against microorganisms and cellular damage from luminal contents (Noah *et al.*, 2011). A third secretory cell found scattered among other epithelial cell types in the gastrointestinal tract are the enteroendocrine cells. The transcription factor neurogenin3 is required for differentiation of these cells, which in response to various stimuli can secrete hormones that regulate digestion into the local environment or into the bloodstream (Jenny *et al.*, 2002). The hormones produced define the subtypes, including K-cells and L-cells in the small intestine, and G-cells in the stomach (May and Kaestner, 2010). Another rare cell type located in the respiratory and intestinal epithelium are the tuft cells, which are characterized by thick, long projections of microvilli from the apical surface and corresponding dense arrays of apical actin filaments. Beyond the transcription factor Gfi1b, few cell-specific markers have been identified (Bjerknes *et al.*, 2012). Assignment of tuft cells to the secretory lineage

Figure 1 Transmission electron micrograph of a goblet cell in the small intestine. Goblet cells contain granules near the apical surface that contain mucin (yellow arrow heads), which are secreted into the intestinal lumen to generate the protective mucus layer. The tight junctions (green arrow head) and desmosomes (blue arrow head) of the apical junctional complex can be seen between the goblet cell and neighboring enterocytes, the absorptive epithelial cell type of the intestine. The enterocytes display prominent microvilli (red arrow head) on the apical surface. Scale bar = 5 μ m.

remains controversial, as development of tuft cells is independent of transcription factors essential for other secretory cell types, such as *Neurog3*, *Sox9*, and *Spdef* (Gerbe *et al.*, 2012). Tuft cells are potentially chemosensory cells, but their role remains largely undefined (Gerbe *et al.*, 2012).

In addition to secretory cells, other cell types can be found in the gastrointestinal tract including M cells. Microfolds, rather than microvilli, cover the apical surface of these cells and give them their name. Differentiation of these cells is dependent on the cytokine RankL and the transcription factor SpiB (De Lau *et al.*, 2011). M cells are found in specialized sections of the intestinal epithelium, the Peyer's patches, which are discrete collections of epithelial cells located above the gut-associated lymphoid tissue (GALT) (Randall *et al.*, 2008). The M cells within the Peyer's patches are critically involved in immunity in that they are an interface between the luminal contents and the tissue-associated immune cells.

The final and most prevalent epithelial cell type in the small intestine and colon is the enterocyte. As these simple columnar cells migrate out of the crypt base, they maintain active Notch signaling and repress the transcription factor Math1 (Barker *et al.*, 2007). In this way, they avoid differentiation into a secretory lineage and become absorptive cells. Microvilli cover the apical surface of enterocytes (Figure 1), greatly increasing the surface area by which these cells can transport and absorb nutrients from the lumen. Enterocytes are responsible for the uptake of ions, lipids, peptides, sugars, and water and also maintain a physical barrier between the microorganisms in the intestinal lumen and the underlying tissue.

Defense

A basic defense mechanism is to block entry of the pathogen into the body, thereby preventing the establishment of an infection. As discussed earlier, the skin is a formidable wall composed of multiple layers of cells packed closely together. The importance of this defense strategy is illustrated by the dire consequences that follow a breach in this barrier. Prior to the development of the tetanus vaccine, the release of the toxin produced by *Clostridium tetani* into the bloodstream was a major cause of lethality following wounding (Bizzini, 1979). Insect bites represent another common type of breach in the skin. Diseases such as malaria and dengue fever are caused by parasites and viruses carried by mosquitoes and account for a staggering number of deaths each year (Murray *et al.*, 2012; Guzman *et al.*, 2010). Still, the skin blocks the entry of many infectious agents into our body and prevents the rest of the immune system from being overwhelmed. Simple epithelium must also engage in defense. In the lungs, the ciliated cells of the respiratory epithelium work together with goblet cells as part of the mucociliary escalator (Lillehoj *et al.*, 2013). The cilia beat in concert to push pathogens and harmful particles trapped in the mucus out of the airway. The mucus-trapped material is either expectorated or swallowed into the stomach where the low pH can kill pathogens. Thus, the parietal cells of the stomach that maintain this low pH can also be considered part of the epithelial defense strategy.

These defense mechanisms are rudimentary in comparison to the chemical warfare that is prominent in the lower gastrointestinal tract. The intestinal epithelium produces or transports an immense amount of mucus, antibodies (immunoglobulins), and antimicrobial peptides – approximately 3 g of immunoglobulin A (IgA) is secreted into the intestinal lumen daily and accounts for the majority of immunoglobulins in the human body (Hooper, 2009; Fagarasan and Honjo, 2003). All epithelium engage in this type of chemical warfare to a certain extent, but to understand why the intestine in particular relies heavily on these long-range weapons requires discussion of its unique vulnerabilities. As mentioned earlier, the intestinal epithelium is one-cell-thick to accommodate nutrient acquisition, and the enterocytes turn over rapidly. This thin epithelial layer is in constant proximity to a large number of an assortment of microbes in the intestinal lumen. The human body is home to 10^{14} or greater commensal bacteria, the majority of which is found in the distal parts of the intestine (Honda and Littman, 2012). While collectively referred to as commensals, these microbes are heterogeneous and represent >1000 species. The gram-positive anaerobic *Lactobacillus* and *Bifidobacterium* species are well known for assisting with digestion of carbohydrates and producing vitamins that cannot be synthesized by human cells (LeBlanc *et al.*, 2013). The gram-negative *Bacteroides* genus and *Escherichia coli* are also ubiquitous and provide metabolites for the host, but certain strains express virulence factors and are associated with inflammatory bowel disease (IBD) and colon cancer (Packey and Sartor, 2009; Wu *et al.*, 2009; Arthur *et al.*, 2012). The intestinal epithelium is also exposed to a continual flow of foreign material that can include pathogenic bacteria such as *Salmonella enterica* and *Listeria monocytogenes*. These and many other infectious agents enter the digestive tract when we consume food and water, and cause diarrhea as well as more severe complications upon dissemination to other organs (Preidis *et al.*, 2011). Therefore, the intestinal epithelium is a barrier between the rest of our body and a spectrum of microbes that can be transient or stable, and range from pathogenic to innocuous, or even beneficial.

Despite the obvious danger that penetration of this barrier represents, the intestinal immune system cannot indiscriminately remove all bacteria since commensals provide benefits beyond digestion. Commensal bacteria as a whole are necessary for occupying a niche that would otherwise be exposed to pathogenic bacteria, a phenomenon referred to as colonization resistance. This function of commensals is exemplified by *Clostridium difficile* infection. *Clostridium difficile* is a gram-positive spore-forming bacterium that can be found in the intestines of healthy individuals. However, treatment with antibiotics, particularly during hospital visits, can remove bacteria in the colon and create opportunities for *C. difficile* to overgrow (Pacheco and Johnson, 2013). *Clostridium difficile* produces enterotoxins that cause diarrhea and pseudomembranous colitis, and is the leading cause of death due to gastrointestinal infection in the United States (Hall *et al.*, 2012). Remarkably, the most promising strategy for treating recurrent *C. difficile* infection is fecal transplantation involving the transfer of intestinal bacteria from a healthy donor (Kassam *et al.*, 2013). The efficacy of this intervention provides additional evidence that commensal bacteria are critical for

preventing opportunistic infections. For this and other reasons, the goal of the intestinal epithelium is to maintain a mutually beneficial coexistence with commensal bacteria rather than creating a sterile environment that leaves the host susceptible.

How does the intestinal epithelium fulfill this task while functioning as a barrier for a surface area that is 10 times larger than that of the skin? Two general strategies are apparent – maintaining distance with the bacterial flora and calibrating the immune response. A 50 μm ‘demilitarized zone’ has been described in mice that separates most commensal bacteria from the underlying epithelium (Vaishnava *et al.*, 2011). This separation is achieved in part by the secretion of an antimicrobial molecule termed Reg3 γ by Paneth cells and enterocytes. Also, both cell surface-associated and secreted mucins create the mucus layer of the intestine that extends this distance further by forming a net (Sheng *et al.*, 2012). Mice deficient in Muc2, the predominant mucin produced by intestinal goblet cells, are highly susceptible to intestinal inflammation in a variety of instances due to a breakdown in this extended barrier (Heazlewood *et al.*, 2008; Van Der Sluis *et al.*, 2006; Bergstrom *et al.*, 2010). Epithelial cells also transport antibodies to the lumen that are produced by plasma B cells in the lamina propria, the connective tissue below the epithelium. The polymeric IgA receptor (pIgR) can bind IgA on the basolateral side, undergo endocytosis, and release IgA into the lumen upon transport to the apical surface (Fagarasan and Honjo, 2003). These and many other secreted molecules create a chemical gradient that reduces the density of bacteria near the epithelium.

This strategy of creating distance is complemented by a second strategy, which is to ignore innocuous microbes and act swiftly in the face of a bona fide threat. The epithelium plays an active role in this process as well by helping to maintain a tolerogenic adaptive immune response under steady-state conditions. Adaptive immune responses are generated when lymphocytes (B and T cells) become activated upon recognition of foreign material presented by antigen-presenting cells. M cells actively transport luminal contents to CD103⁺ dendritic cells, a type of antigen-presenting cell that is abundant in the small intestinal lamina propria (Honda and Littman, 2012). At the same time M cells are delivering antigens to dendritic cells in the underlying GALT, enterocytes are absorbing and processing vitamin A precursors (Von Lintig, 2012). CD103⁺ dendritic cells display increased retinal dehydrogenase activity to convert this vitamin A (retinal) into retinoic acid (Agace and Persson, 2012). Retinoic acid, along with TGF β , favors the conversion of lymphocytes into noninflammatory IgA secreting plasma cells and regulatory T cells (Tregs) (Agace and Persson, 2012; Honda and Littman, 2012). Thus, in the absence of inflammatory signals, the system is rigged to recognize commensal bacteria and other foreign material as innocuous agents rather than a threat. There are most likely many additional mechanisms by which epithelial cells induce a tolerogenic state that are yet to be uncovered. For example, recent studies have revealed unexpected properties of goblet cells and mucins in delivering antigens to CD103⁺ dendritic cells and inhibiting inflammatory gene expression (McDole *et al.*, 2012; Shan *et al.*, 2013).

In contrast to this immuno-suppressive function, the intestinal epithelium promotes immune responses by expressing

cell adhesion molecules that attract dendritic cells as well as intra-epithelial lymphocytes (IELs). Unlike traditional T cells, IELs are imbedded in the epithelial layer and poised to respond to threats without a prolonged maturation process (Cheroutre *et al.*, 2011). Also, toxins and virulence factors produced by pathogens can act on the epithelium and trigger inflammatory signals leading to recruitment and differentiation of pro-inflammatory dendritic cells (Honda and Littman, 2012). For instance, bacterial adhesion is a virulence strategy that can directly trigger inflammatory signaling in intestinal epithelial cells (Boyle and Finlay, 2003). Through these various mechanisms, many of which involve the epithelium, the intestine can exist in a paradoxical state where it is generally tolerogenic but simultaneously primed for a swift inflammatory response toward pathogens.

Loss of Barrier Function in Disease

The importance of the epithelial barrier becomes obvious when we observe the consequences of failure during disease conditions. A ubiquitous virulence strategy utilized by food- and water-borne bacterial pathogens is the secretion of toxins that disrupt tight junctions, which allows the microorganism access to the favorable environment on the other side of the barrier (Berkes *et al.*, 2003). These toxins also interfere with ion transporters and directly disrupt the fluid absorbing properties of enterocytes. For instance, the cholera toxin produced by *Vibrio cholerae* causes efflux of chloride ions via phosphorylation of the cystic fibrosis transmembrane conductance regulator (CFTR), subsequently leading to secretion of water, sodium, and potassium (Field *et al.*, 1989). Therefore, enteric infections are associated with diarrhea and dehydration, which remains one of the leading causes of infant mortality (Preidis *et al.*, 2011). As mentioned above, attachment to the intestinal epithelium represents another common virulence strategy that can lead to effacement, disorganization, and hyperproliferation of the epithelium, and requires quick resolution to prevent catastrophic breakdown of the barrier (Figure 2). Some pathogens readily disseminate throughout the host upon ingestion. In the case of typhoid fever, a deadly disease that affects over 16 million people annually, *Salmonella typhi* travels from the intestine through lymph and blood to reach the liver, spleen, and kidneys (Parry *et al.*, 2002). Epithelial barriers other than that of the intestine are also commonly overcome by pathogens. Urinary tract infections can progress to pyelonephritis when bacteria and viruses that infect the bladder, most commonly *E. coli*, spread to one or both kidneys (Ragnarsdottir and Svanborg, 2012). During sexual transmission of human immunodeficiency virus (HIV), the virus is thought to reach its target T cells by hitching a ride on dendritic cells in the mucosa (such as the vaginal surface) that migrate to lymphoid tissues (Wu and KewalRamani, 2006). In developing countries, over 200 million individuals are infected by Schistosome parasites, whose larvae found in freshwater burrow through the skin and mature in various organ tissue to cause a range of symptoms (King *et al.*, 2005).

Mendelian genetic disorders that directly disrupt the barrier are rare, perhaps reflecting the general importance of maintaining

Figure 2 Bacterial adhesion can disrupt the epithelium. A single layer of epithelial cells demarcated by E-cadherin form invaginations referred to as crypts. *Citrobacter rodentium* is a model mouse pathogen related to *E. coli* that attaches to the apical surface of the intestinal epithelium. This adhesion causes an uneven appearance in the surface epithelium due to effacement as well as a hyper-proliferative response that leads to crypt elongation. The left panel shows an immuno-fluorescence microscopy image of colonic crypts from uninfected mice. The right panel shows the dramatic restructuring of the colonic crypts following infection with *C. rodentium* expressing green fluorescence protein (GFP). Red = E-cadherin, blue = nuclei, green = GFP-*C. rodentium*, and asterisks = lumen. Scale bar = 40 μ m.

epithelial barriers. The tight junction complex in the inner ear epithelium is required for maintaining differential ion concentrations between the inner and outer fluids of the cochlea, and thus recessive mutations in *Claudin-14* lead to congenital deafness (Wilcox *et al.*, 2001; Ben-Yosef *et al.*, 2003). Also, *Claudin-16* (*paracellin-1*) mutations lead to familial hypomagnesemia with hypercalciuria and nephrocalcinosis due to defects in paracellular transport in the kidney (Simon *et al.*, 1999). In contrast, IBD is a prominent example of barrier dysfunction involving complex genetic and environmental factors (McGuckin *et al.*, 2009; Khor *et al.*, 2011). IBD, which includes Crohn's disease and ulcerative colitis, is linked to over a hundred polymorphisms that are thought to disrupt the tolerogenic environment in the intestine discussed above (Jostins *et al.*, 2012). Although the involvement of any specific intestinal microbe remains controversial (Packey and Sartor, 2009), there is consensus that a loss of tolerance toward commensals leads to recurring inflammatory destruction of the epithelium. In addition to direct epithelial damage, inflammatory cytokines such as tumor necrosis factor (TNF)- α and interferon (IFN)- γ can increase intestinal permeability by inducing myosin light chain kinase (MLCK) to destabilize tight junctions (McGuckin *et al.*, 2009). Commensal bacteria that are otherwise innocuous may gain access past the epithelium to exacerbate or sustain ongoing inflammation. Additionally, patients frequently display altered levels of Paneth cell defensins and goblet cell mucins (Wehkamp *et al.*, 2005; Sheng *et al.*, 2012). Thus, epithelial dysfunction appears to be a key feature of IBD, although some of these abnormalities may be secondary to defects in lymphocytes and other white blood cells.

Perspective

Major research efforts in the field of epithelial biology include examination of how epithelia in various organs differ in their developmental program, interactions with microbes, and contributions to disease. These efforts have been greatly

facilitated by technological innovations such as organ cultures, high-throughput sequencing, increased computational capacities to analyze complex data, and genetic models that allow cell type-specific manipulations. The application of these techniques to IBD has certainly improved our understanding of disease pathogenesis, but has also increased our knowledge of cell biology. For instance, large-scale population genetic studies have led to the identification of a highly common polymorphism in *Atg16L1*, a gene that is essential for macroautophagy. Macroautophagy (or autophagy) is a pathway by which double membrane vesicles sequester cytosolic material and target the contents for degradation upon fusion with the lysosome (Levine *et al.*, 2011). Mice deficient in *Atg16L1* and other autophagy genes in the intestinal epithelium display profound defects in Paneth cell granule packaging (Cadwell *et al.*, 2008, 2009), mucin secretion by goblet cells (Patel *et al.*, 2013), and degradation of bacteria in enterocytes (Benjamin *et al.*, 2013; Conway *et al.*, 2013). Importantly, the recent generation of mice that delete loxP flanked alleles in Paneth cells (defensin 6-Cre mice) has allowed investigators to take this a step forward. Dual deletion of *Atg16L1* and *Xbp1*, an ER stress gene that has also been linked to IBD, leads to dramatic intestinal inflammation (Adolph *et al.*, 2013). Hence, a cell-intrinsic defect in a secretory epithelial cell type can directly lead to intestinal disease. Nevertheless, basic research of the autophagy pathway reminds us that the epithelium does not exist in a vacuum. Among other immune functions, autophagy has also been shown to have a role in dampening inflammatory cytokine expression in macrophages (Saitoh *et al.*, 2008). Also, the Paneth cell dysfunction in *Atg16L1* deficient mice is only apparent in the presence of murine norovirus (MNV), an intestinal virus that is endemic in mouse colonies (Cadwell *et al.*, 2010). Surprisingly, these same *Atg16L1* deficient mice are incredibly resistant to intestinal bacterial infection due to an enhanced immune response (Marchiando *et al.*, 2013). Thus, it is still unclear why a basic membrane trafficking pathway is linked to a disorder that features the breakdown of

the intestinal epithelial barrier following inflammation. One intriguing possibility is that the same cell biological pathway is important for barrier function in both epithelial and non-epithelial cells, but the exact contribution and mechanism are distinct.

These challenges facing the IBD field highlight the need for multidisciplinary approaches in investigating epithelial biology. In addition to technological progress, investigators are increasingly engaging in both small-scale collaborations as well as giant multi-institutional efforts. The generation of a reference catalog of commensal bacteria that colonize epithelial surfaces, the human microbiome project, will be an incredible resource for research into how distinct epithelia interact with microorganisms ([Human Microbiome Project Consortium, 2012](#)). In comparison, we still lack an appreciation of how fungi, parasites, and viruses maintain or disrupt epithelial function. Another topic that requires better resolution is the contribution of epithelia to interindividual variability. The answer to this question will have significant medical impact in the context of personalized medicine and spread of infectious agents such as *Staphylococcus aureus*. Antibiotic resistant strains of *S. aureus* have devastated the healthcare system by causing a range of diseases once it penetrates the epithelial barrier, but this bacterium also colonizes the skin as an innocuous commensal in about one-third of individuals ([Lowy, 1998](#)). Advances in technology and the way investigators approach difficult problems through teamwork will solve many of these tough challenges in epithelial biology and barrier function in the years to come.

Glossary

Adaptive immune response The later phase of an immune response that involves T cells and B cells and is responsible for generating immune memory; each T or B cell expresses receptors with a unique molecular structure that are only activated by specific molecules (antigens), which allows them to induce antigen-specific responses.

Antigen presenting cells Cells that display antigens such as peptides acquired from degraded microbes on their surface to activate T cells; dendritic cells are particularly effective at antigen presentation.

Innate immune response The early phase of an immune response when microbes and other threats are detected by cells such as neutrophils, macrophages, and dendritic cells to initiate an immune response; involves nonspecific

detection of molecular patterns commonly associated with microbial components by 'pattern recognition receptors'; microbes acquired during this phase are destroyed and processed to derive antigen molecules for presentation to T cells to activate the 'adaptive immune response.'

Opsonization Binding of serum proteins such as complement and antibodies to the surface of microbes and cells to enhance their detection and uptake by phagocytic cells.

Pattern recognition receptors Receptors (such as Toll-like receptors and Dectin-1) used by immune cells to detect microbial components.

Phagocytosis Receptor-mediated uptake of particulate targets $>0.5\ \mu\text{m}$ by a process of membrane engulfment driven by the actin cytoskeleton.

Introduction

Cell-cell contact mediated by the interaction of proteins on the surface of neighboring cells enables intercellular communication. Large multi-protein complexes can form stable connections or 'synapses' between cells that in some cases can last hours, days, or even years. Neurons, for example, transmit electrical and chemical signals by forming synapses with muscle cells or other neurons. In the immune system, activation of an adaptive immune response is dependent on the formation of 'immunological synapses' between antigen presenting cells (APC) (such as dendritic cells) and T cells (Figure 1). Recent studies have shown that the responses of phagocytic cells of the innate immune system are also controlled by synapses: 'phagocytic synapses' (Dustin, 2012; Goodridge *et al.*, 2011; Yamauchi *et al.*, 2012; Figure 1).

Phagocytosis is the process by which cells such as macrophages, dendritic cells, and neutrophils engulf large ($>0.5\ \mu\text{m}$) particulate matter, including microbes, apoptotic cells, and cellular/extracellular matrix debris. Phagocytic receptors are activated when they detect target particles. Their intracellular signals instruct cytoskeletal rearrangement to coordinate particle internalization. Several receptors that detect microbial components can induce phagocytosis of microbes (Figure 1). For example, when Dectin-1 on the surface of a macrophage detects β -glucan in the wall of a fungal yeast cell, it triggers phagocytic internalization of the yeast by the macrophage. Macrophages are also instructed to phagocytose 'opsonized' targets that are coated with antibodies (immunoglobulins, Ig) or complement proteins found in serum. For example, the Fc γ receptor (Fc γ R) detects IgG-opsonized microbes to trigger internalization and microbial killing.

Figure 1 Immunological and phagocytic synapses. Formation of immunological synapses between dendritic cells (or other APCs) and T cells are required for T cell activation. The TCR is only activated when it detects its cognate antigen presented by MHC molecules on the dendritic cell surface. Similarly, phagocytic synapses permit the activation of the phagocytic receptors Dectin-1 and Fc γ R to induce target phagocytosis and cytokine production. Dectin-1 on the surface of a macrophage (or neutrophil or dendritic cell) detects β -glucans in fungal cell walls. Fc γ R detects the Fc portion of IgG coating target particles such as microbes.

In addition to phagocytosis, intracellular signals generated by Dectin-1 and Fc γ R also induce the production of inflammatory mediators such as cytokines. Moreover, macrophages and dendritic cells use phagocytosis to acquire antigens for presentation to T cells to initiate adaptive immune responses. As discussed below, phagocytic synapses formed when Dectin-1 and Fc γ R encounter target particles control the initiation of phagocytosis and cytokine production to ensure that these responses are not inadvertently triggered.

Dectin-1 Activation by β -Glucans

Dectin-1 detects fungal β -glucans (specifically β -1,3-glucans) and plays key roles in immune defense against fungi such as *Candida albicans* and *Aspergillus fumigatus* (Drummond and Brown, 2011; Goodridge *et al.*, 2009). β -Glucans are large polymers of D-glucose and are a major structural component of fungal cell walls. Upon detection of β -glucans in fungal cell walls, Dectin-1 signaling triggers phagocytic uptake of fungal cells, the production of reactive oxygen species (oxidative burst response) to kill the internalized fungi, and the generation of inflammatory mediators to recruit and activate other immune cells. Unlike most microbial receptors, however, Dectin-1 is only activated when it detects its agonist in particulate form, for example, β -glucan in a yeast cell wall or β -glucan-coated latex beads (Goodridge *et al.*, 2011). Soluble β -glucans fail to activate the receptor. Even very large, highly polymerized soluble β -glucans that simultaneously bind and cross-link lots of receptor molecules are unable to activate Dectin-1. This is in contrast to Toll-like receptor 2, for example, which is activated in response to microbial lipopeptides in soluble form as well as in the context of a microbial cell wall.

This feature of Dectin-1 is thought to limit the responses of macrophages to direct encounters with β -glucan-containing fungal cells. Dectin-1 instructs responses that other microbial receptors such as Toll-like receptors do not (phagocytosis and a strong oxidative burst response). It is therefore important to prevent collateral damage caused by the initiation of powerful antimicrobial and inflammatory responses in the absence of an immediate threat, for example, when macrophages detect β -glucans shed from yeast that are not in the immediate vicinity. The phagocytic synapse model was proposed to explain how Dectin-1 can distinguish between soluble and particulate β -glucans (Goodridge *et al.*, 2011).

Dectin-1 signals in a similar manner to the T cell antigen receptor (TCR), which transmits signals to activate T cells by associating with CD3 molecules. CD3 molecules have immunoreceptor tyrosine-based activation motifs (ITAMs) which become phosphorylated on tyrosine residues by members of the Src family of tyrosine kinases (SFKs) when the antigen-specific TCR detects its cognate antigen (Figure 2). Zap70 kinases are then recruited to the phosphorylated ITAM tyrosines to propagate the signal. Dectin-1 has an ITAM-like motif (called a hemITAM) in its cytoplasmic tail, which is phosphorylated by SFKs when Dectin-1 detects particulate or immobilized β -glucans (Figure 2). The Zap70-related kinase Syk is then recruited to Dectin-1 to transduce downstream signaling.

As noted above, Dectin-1 does not induce responses when it binds soluble β -glucans. Likewise, the TCR does not respond to

soluble antigen, but is only activated when it detects its antigen in the context of major histocompatibility complex (MHC) molecules on the surface of APCs such as dendritic cells. When an antigen is presented to the TCR by MHC, TCR molecules cluster and a large multi-protein complex forms at the contact site between the dendritic cell and the T cell, resulting in a stable interaction between the two cells – an immunological synapse (Figure 1; Dustin, 2012; Dustin and Depoil, 2011). Within the immunological synapse, membrane-intrinsic and recruited proteins are arranged in a bull's-eye pattern to permit TCR signaling and T cell activation. One of the key events in the formation of the immunological synapse is the isolation of CD45 molecules away from TCR molecules. CD45 is a membrane-intrinsic tyrosine phosphatase that is initially required for SFK activation but subsequently plays a negative regulatory role by dephosphorylating the ITAM tyrosines and other signaling molecules activated by the SFKs and Zap70. Sequestration of CD45 away from the TCR therefore permits the generation of a productive TCR signal.

A similar mechanism controls the initiation of Dectin-1 signaling – the phagocytic synapse (Goodridge *et al.*, 2011; Figure 3). In macrophages, CD45 and a related tyrosine phosphatase CD148 regulate Dectin-1 activation by first permitting SFK activation and subsequently negatively regulating Dectin-1 signaling via SFKs and Syk. When a macrophage engages a β -glucan-containing particle (e.g., a yeast cell or a β -glucan-coated bead), Dectin-1 receptor molecules cluster at the contact site and their activation is evidenced by the recruitment of activated SFKs and Syk. This is accompanied by the movement of CD45 and CD148 away from the clustered receptors to permit continued Dectin-1 signaling. Confocal microscopy reveals a bull's-eye pattern of molecules on the surface of the cell with clustered Dectin-1 and active SFKs and Syk in the central zone and excluded CD45/CD148 around the outside (Figures 4 and 5).

Fc γ R Activation by Immunoglobulin G (IgG)

Phagocytic synapses also control Fc γ R-mediated uptake of antibody-opsonized targets (Yamauchi *et al.*, 2012; Figures 3 and 4). Like Dectin-1, Fc γ R signaling triggers actin-driven phagocytosis of target particles, as well as the induction of an oxidative burst response and production of inflammatory mediators. Therefore, Fc γ R must also distinguish between soluble and particulate forms of its agonist so that it will transduce signals upon detection of IgG-opsonized cells (e.g., microbes, tumor cells) but ignore free IgG molecules. When macrophages engage IgG-opsonized cells or IgG-coated beads, Fc γ R clustering is observed at the contact site. Signaling is initiated by SFK phosphorylation of ITAMs to permit Syk recruitment and activation (Figure 2). CD45 and CD148 regulate Fc γ R signaling (Zhu *et al.*, 2008) and CD45 exclusion is a feature of Fc γ R phagocytic synapse formation (Yamauchi *et al.*, 2012). CD148 is also likely to be excluded from the Fc γ R phagocytic synapse.

Studies of Fc γ R activation revealed another key player in phagocytic synapse formation – myosin II (Yamauchi *et al.*, 2012). Myosin II, an ATP-driven motor protein that generates contractile forces along actin filaments, regulates Fc γ R

Figure 2 ITAM signaling by the TCR, Dectin-1, and Fc γ R. The TCR, Dectin-1, and Fc γ R signal via ITAMs or ITAM-like motifs. The TCR signals via ITAM-containing CD3 molecules. ITAMs are motifs containing dual tyrosines that are phosphorylated by SFK upon ligand binding, receptor clustering, and synapse formation. A dual phosphorylated CD3 ITAM forms a docking site for the tyrosine kinase Zap70, which binds via its dual SH2 domains. Zap70 is then activated by phosphorylation to initiate downstream signaling. Dectin-1 and Fc γ R on the macrophage surface signal in a similar manner, but they recruit a related kinase called Syk instead of Zap70. Dectin-1 does not possess a conventional ITAM. Instead, an ITAM-like motif (called a hemITAM) in its intracellular tail contains a single tyrosine residue that is phosphorylated by SFK. Syk is then recruited to phosphorylated Dectin-1 homodimers.

phagocytosis by controlling the actin dynamics responsible for pseudopod extension and target engulfment (Araki, 2006). It also plays a key role in the formation of the immunological synapse (Dustin, 2012), so its involvement in Fc γ R phagocytic synapse formation illustrates another parallel between the two synapse models. Following Fc γ R clustering and SFK activation, myosin II is required for ITAM phosphorylation and Syk activation to coordinate actin polymerization (Yamauchi *et al.*, 2012).

CD45 associates with actin filaments via spectrin and ankyrin, which control lateral movement of CD45 in the plasma membrane (Cairo *et al.*, 2010; Pradhan and Morrow, 2002). Thus it seems likely that actin dynamics are responsible for CD45 exclusion, although phagocytic synapse formation probably precedes pseudopod extension, since the signals that drive large-scale cytoskeletal movement to form pseudopods are presumably dependent on CD45 exclusion. Spectrin is localized to the plasma membrane via interactions with PI-4,5-bisphosphate (PIP₂), which is also thought to participate

in the formation of the Fc γ R phagocytic synapse. Given the parallels between Dectin-1 and Fc γ R signaling (Goodridge *et al.*, 2012), it is likely that myosin II regulates the Dectin-1 phagocytic synapse in a comparable manner.

The Phagocytic Synapse Model

The current phagocytic synapse model (Figure 3) therefore suggests that when Dectin-1/Fc γ R molecules on the surface of a macrophage initially detect a soluble or particulate ligand, a small number of receptor molecules cluster, triggering low-level SFK activation and ITAM phosphorylation. Although initially required to permit SFK activation, CD45 and CD148 subsequently limit receptor signaling by ITAM dephosphorylation, thereby preventing receptor activation in response to soluble agonists. However, if a particle is engaged by a large number of receptor molecules and myosin II is recruited, actin will begin to polymerize near the clustered receptors.

Figure 3 Model of phagocytic synapse formation to permit Dectin-1 and Fc γ R activation. (a) Receptors begin to cluster upon initial recognition of particulate targets by Dectin-1/Fc γ R. At the early stages, CD45 and CD148 are initially required for SFK activation (they remove an inhibitory tyrosine phosphorylation from SFK). However, the continued presence of CD45 and CD148 prohibits productive ITAM signaling because they dephosphorylate ITAMs and inactivate SFK, Syk, and downstream signaling molecules. Therefore, CD45 and CD148 must be isolated from the clustered receptors to permit productive signaling, which results in target internalization and other responses such as cytokine production. The isolation of CD45 (and probably CD148) away from clustered Fc γ R is controlled by myosin II. It is likely that myosin II also controls CD45/CD148 movement during formation of the Dectin-1 phagocytic synapse. When soluble ligands such as β -glucan fragments shed from fungal cell walls bind to the receptors they do not induce phagocytic synapse formation. Consequently, they do not trigger receptor activation, phagocytosis, and cytokine production. (b) In addition to CD45/CD148, SIRP α also negatively regulates Fc γ R-mediated phagocytosis upon detection of its ligand CD47 on target cells. SIRP α has an ITIM in its cytoplasmic tail, which recruits the tyrosine phosphatases SHP-1 and SHP-2 following CD47 binding. The SHP phosphatases antagonize ITAM signaling by dephosphorylating ITAMs/ITAM-signaling molecules to block Fc γ R signaling and prevent phagocytosis.

Figure 4 Phagocytic synapse ‘bull’s-eyes.’ A ‘bull’s-eye’ pattern of staining is observed when phagocytic synapses are visualized by confocal microscopy using antibodies against the receptors, intracellular signaling molecules, and CD45/CD148. Prior to target binding, the receptors and CD45/CD148 are distributed evenly over the cell surface. Upon target binding, the receptors cluster in the center of the ‘bull’s-eye’ and are shown to be actively signaling by the presence of phosphorylated SFK and Syk, and detection of tyrosine-phosphorylated proteins (likely the receptor ITAMs, SFK, Syk, and downstream signaling proteins). CD45 and CD148 are now excluded from this central region to allow productive receptor signaling to drive phagocytosis and cytokine production.

Figure 5 Confocal imaging of Dectin-1 phagocytic synapses. (a) Frames taken at 30 s intervals from a movie of phagocytic synapse formation upon detection of a β -glucan-containing yeast particle (whole glucan particle, WGP) by a macrophage. When the particle (blue) is detected by the cell, CD45 (red) is cleared from the site of particle attachment as Dectin-1 receptors (green) cluster. (b) 3-D isosurface modeling of two Dectin-1 phagocytic synapses reveals ‘bull’s-eye’ distribution of CD45 (red) and active Syk (phosphorylated Syk, pSyk; green) at the macrophage surface. Bound particles are not shown. Reproduced with permission from Goodridge, H.S., *et al.*, 2011. Activation of the innate immune receptor Dectin-1 upon formation of a ‘phagocytic synapse.’ *Nature* 472, 471–475.

As myosin II further orchestrates actin dynamics, CD45 and CD148 are dragged away from the clustered receptors and pseudopods begin to extend around the particle. This establishes a positive feedback loop to amplify Dectin-1/Fc γ R signaling by preventing dephosphorylation of the receptor ITAMs. This mechanism is also likely to regulate signaling by these receptors in other phagocytic cells such as dendritic cells and neutrophils.

The early events that drive phagocytic synapse formation are still unclear. The phagocytic synapse may originate from the coalescence of small clusters of Dectin-1/Fc γ R molecules interacting with an immobilized ligand on the same particle. Soluble agonists may be able to trigger receptor clustering and perhaps even a low level of signaling, but are ultimately unable to activate sufficient signaling to induce a productive phagocytic response because the ligand molecules they detect

are not physically connected to one another and so are unable to induce the receptor aggregation required for synapse formation and isolation of the suppressive CD45/CD148 phosphatases. Another possibility, hypothesized from studies of the immunological synapse, is that Dectin-1 and Fc γ R might act as mechanosensors that detect forces generated by interaction with their immobilized ligands.

It is likely that other molecules are also segregated when phagocytic synapses form. Biological targets (microbes, apoptotic cells, tumor cells, etc.) are complex in composition, so multiple receptors are usually involved in their detection. Even though these receptors may not instruct phagocytic internalization, their presence in the synapse may affect the efficiency of target binding and the rate of uptake (Goodridge *et al.*, 2012). In particular, integrins act as adhesion molecules and as sensors of microbial components and opsonizing complement proteins, and can themselves instruct phagocytosis. Indeed, integrins are involved in the formation of the immunological synapse. It is therefore likely that they also participate in phagocytic synapse formation and organization, and since they signal via tyrosine kinases they may also be

regulated by CD45/CD148. It is not yet clear whether other phagocytic receptors are regulated in the same way as Dectin-1 and Fc γ R. However, as discussed below, evidence from studies of phagocytosis of apoptotic cells and tumor cells suggests that this may be the case and provides another mechanism by which the phagocytic synapse can be regulated.

Regulation of the Phagocytic Synapse by CD47

Phagocytosis is not only important for the control of microbial invaders, but also for clearance of 'self' cells to maintain tissue homeostasis by removing senescent or damaged cells (including tumor cells), and for tissue remodeling. To distinguish between cells that they should phagocytose and cells that they should ignore, macrophages look for 'eat me' and 'don't eat me' signals. For example, calreticulin is normally located in the endoplasmic reticulum, but apoptotic cells and tumor cells display it on the cell surface where it represents an 'eat me' signal that is detected by low-density lipoprotein-related protein (LRP, also known as CD91) (Chao *et al.*, 2012).

Figure 6 Regulation of the Fc γ R phagocytic synapse by CD47-SIRP α . CD47 on the surface of target cells delivers a 'don't eat me' signal to macrophages via binding to SIRP α to prevent phagocytic uptake of the CD47-bearing cell. Senescent and apoptotic cells decrease CD47 expression and/or increase the expression of 'eat me' signals such as calreticulin to encourage their clearance. However, tumor cells up-regulate CD47 expression to avoid being phagocytosed, even in the presence of 'eat me' signals such as calreticulin or opsonizing antibodies. Therapeutic strategies that target CD47 are being explored for cancer treatment to prevent SIRP α -mediated suppression of phagocytic synapse formation and promote tumor cell uptake. Coadministration of anti-CD47 antibodies that block the 'don't eat me' signal along with opsonizing antitumor antibodies that deliver an 'eat me' signal to activate Fc γ R phagocytic synapses may be particularly effective.

When immunoglobulins and complement proteins attach to target cells (opsonization) they also deliver 'eat me' signals to instruct phagocytosis via Fc receptor- and complement receptor-mediated uptake, respectively. CD47, on the other hand, delivers a 'don't eat me' signal to macrophages (Oldenborg, 2013; Oldenborg *et al.*, 2000). CD47 is expressed on all cells but at variable levels. Healthy red blood cells, for example, avoid being phagocytosed by splenic macrophages due to their high expression of CD47. As red blood cells age, however, their expression of CD47 decreases and they are cleared by splenic macrophages.

The macrophage receptor that detects CD47 is called signal regulatory protein α (SIRP α). SIRP α signals via an immunoreceptor tyrosine-based inhibition motif (ITIM). Activated ITIM-containing receptors oppose signals generated by ITAM-containing receptors by recruiting the tyrosine phosphatases SHP-1 and SHP-2 to dephosphorylate the tyrosine-phosphorylated proteins that transduce ITAM signals (Figure 3(b)). Indeed, CD47-SIRP α signaling has been shown to restrict Fc γ R-mediated phagocytic uptake of IgG-opsonized cells by decreasing the tyrosine phosphorylation and accumulation of myosin II, thereby restricting phagocytic synapse formation (Tsai and Discher, 2008). CD47-SIRP α also suppresses target cell uptake by other phagocytic receptors, including complement receptor and LRP (Chao *et al.*, 2010; Tsai and Discher, 2008). These receptors do not appear to signal via ITAMs but the phagocytic signals they transduce have been reported to be driven by tyrosine kinases, which are presumably antagonized by the SIRP α -activated phosphatases. It is possible that CD45 and CD148 also regulate these receptors and that the phagocytic synapse model is not just restricted to phagocytic receptors that signal via ITAMs.

Interestingly, tumor cells often exploit the CD47-SIRP α interaction by up-regulating CD47 expression and using it to evade immune detection (Chao *et al.*, 2012). However, dying tumor cells and even some viable tumor cells also have higher surface expression of the calreticulin 'eat me' signal (Chao *et al.*, 2010, 2012). Blockade of CD47 using antibodies is therefore being investigated as an anticancer treatment to silence the 'don't eat me' signal. Anti-CD47 antibodies block the interaction of CD47 with SIRP α , which allows for the delivery of the calreticulin-LRP 'eat me' signal to trigger tumor cell phagocytosis (Figure 6). Normal cells are not cleared, even in the presence of anti-CD47 antibodies, because they do not express calreticulin at the cell surface so they do not deliver an 'eat me' signal via LRP. Anti-CD47 antibodies could be particularly effective at enhancing phagocytic uptake and destruction of tumor cells when delivered in combination with antibodies specific for tumor antigens, which would opsonize tumor cells to simultaneously deliver an 'eat me' signal to Fc receptors (Chao *et al.*, 2012). Blocking the CD47 signal would favor phagocytic synapse formation to instruct uptake of tumor cells, which is required for tumor antigen acquisition for presentation to T cells to initiate an antitumor immune response.

Summary

The phagocytic synapse provides a model mechanism whereby phagocytic cells are able to identify particulate targets that they need to clear, perhaps kill, and ultimately degrade. It permits phagocytes to ignore soluble material that does not require such treatment, thereby conserving energy and limiting collateral damage that might be induced by powerful inflammatory and immune responses. A more complete understanding of how this mechanism regulates phagocytic receptor signaling will inform the development of novel therapeutic strategies to promote or limit phagocytosis and other downstream immune responses.

The Phagocyte Oxidative Burst

Phagocytes such as polymorphonuclear neutrophils (PMN), monocytes, and macrophages are the first line of host defenses against pathogens such as bacteria and fungi (Nathan, 2006). At the infection site phagocytes recognize and engulf the pathogen. This process involves the binding of specific pathogen-associated molecular patterns (PAMPs) such as peptidoglycans, lipopolysaccharides (LPS), flagellin to their respective cell receptors, namely Toll-like receptors (TLR), and the binding of opsonins (immunoglobulins G (IgG), C3b, and C3bi fragments) to immunoglobulin receptors and integrins (Witko-Sarsat *et al.*, 2000; Lee *et al.*, 2003). The recognition is generally followed by engulfment of the particle which will be surrounded by a membrane envelope which will constitute a vacuole called the phagosome. Engulfment of the bacteria is accompanied by the activation of neutrophils which will lead to their death and destruction following the release of anti-microbial peptides, proteases, and reactive oxygen species (ROS) oxidizing molecules (Roos *et al.*, 2003; Nauseef, 2007). ROS include superoxide anion ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), the hydroxyl radical ($OH^{\cdot}$), and hypochlorous acid (HOCl). They are produced by phagocytes in a powerful 'oxidative burst,' characterized by a rapid, cyanide-insensitive increase in oxygen uptake, an increase in glucose consumption, and abrupt ROS production (Hampton *et al.*, 1998). Superoxide anion ($O_2^{\cdot-}$) is the first molecule produced by nicotinamide adenine dinucleotide phosphate-oxidase (NADPH oxidase) and is the precursor of all the other ROS generated in the phagosome (Figure 1). It is produced by monovalent reduction of oxygen in the following reaction (Babior, 2000):

The Phagocyte NADPH Oxidase NOX2

The enzyme responsible for ROS production is called the phagocyte NADPH oxidase (NOX2) or respiratory burst oxidase (Babior, 1999). The active NADPH oxidase is a multicomponent enzyme system located in the phagosome and plasma membranes of activated cells. It consists of several components, a heterodimer composed of two transmembrane proteins, gp91phox and p22phox (phox: phagocyte oxidase) also called cytochrome b558, and four cytosolic components, p47phox, p67phox, p40phox, and either Rac1 (in monocytes) or rac2 (in neutrophils) (Chanock *et al.*, 1994; Figure 2). The membrane-bound and cytosolic components are separated in the membranes and cytosol respectively in resting cells,

ensuring a dormant unactivated state of NOX2, this last one becoming active only if cells are stimulated (El-Benna *et al.*, 2005). In intact cells, NADPH oxidase activation is accompanied by three important events: (1) the phosphorylation of p47phox, p67phox, p40phox, p22phox, and gp91phox; (2) Rac1/2 activation; (3) cytosolic protein translocation toward the membrane and changes in 'protein-protein' and 'proteins-lipids' interactions (Groemping and Rittinger, 2005; DeLeo and Quinn, 1996).

The vital importance of ROS production by the phagocyte NADPH oxidase was demonstrated by a genetic disease called

Figure 1 ROS reactions in the phagosome. Molecular oxygen (O_2) is reduced by the NADPH oxidase complex to produce superoxide anion ($O_2^{\cdot-}$). Superoxide anions can react with protons to produce hydrogen peroxide (H_2O_2), which is used by the myeloperoxidase enzyme (MPO) to produce hypochlorous acid (HOCL). Superoxide can react with H_2O_2 to produce hydroxyl radical ($OH^{\cdot}$). This reaction can occur in the presence of H_2O_2 and metals such as Fe^{2+} or Cu^{2+} .

Figure 2 The active NADPH oxidase complex. The active NADPH oxidase is composed of a membrane-bound flavocytochrome b558 (composed of gp91phox and p22phox) which binds several cytosolic proteins (p67phox, p47phox, p40phox, and rac2). Activated NADPH oxidase uses cytosolic NADPH to reduce oxygen. (P) denotes phosphorylation.

'chronic granulomatous disease' (CGD) (Kannengiesser *et al.*, 2008). It is an inherited immune deficiency disorder in which phagocytes are unable to produce ROS and thus to eliminate pathogens. Recurrent, often life-threatening bacterial and fungal infections usually start during childhood. CGD results from mutations in the NADPH oxidase component genes, namely the CYBB gene (Xp21) that encodes the gp91phox subunit, the CYBA gene (16q24) that encodes the p22phox subunit, the NCF1 gene (7q11) and NCF2 gene (1q25), which encode p47phox, p67phox, respectively (Roos *et al.*, 1996). The most frequent form of CGD (approximately 70% of all cases) is the X-linked gp91phox-deficient form, followed by the autosomal form deficient in p47phox (approximately 25%). Less frequent forms are autosomal CGD deficient in p67phox (<5%) and p22phox (<5%). Only one case of rac2 gene mutation and one case of p40phox gene mutation have been described, possibly due to the relatively mild clinical phenotype which may preclude diagnostic recognition.

Structure of the Membrane Component, Flavocytochrome b₅₅₈ in Resting Cells

The flavocytochrome b₅₅₈ is the central catalytic membrane-bound component of the NADPH oxidase (Vignais, 2002). It is composed of a glycosylated 91-kDa protein subunit (gp91phox) and a non-glycosylated 22-kDa subunit (p22phox) in a 1:1 complex (Huang *et al.*, 1995; Wallach and Segal, 1996; Figure 3). Both proteins stabilize each other in neutrophils (Yu *et al.*, 1997). The heterodimer is called cytochrome b₅₅₈ for its characteristic spectral absorption peak at 558 nm. In resting cells, the flavocytochrome b₅₅₈ is mostly localized in membranes of specific granules, gelatinase granules, and secretory granules and only 10–20% is present in the plasma membrane (El-Benna *et al.*, 2008). In intact cells, the

flavocytochrome b₅₅₈ alone, without the cytosolic components is in an inactive state not able to transfer electrons.

gp91phox

Gp91phox also called the β -subunit of the flavocytochrome b₅₅₈, is composed of 570 amino acids. This protein of a molecular weight of 65 kDa runs as a broad smear around 91 kDa on sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE) because it is very glycosylated on extracytoplasmic sites. Gp91phox has a short cytoplasmic N-terminal sequence (Paclet *et al.*, 2004), predicted six transmembrane α -helices which bind two hemes and a C-terminal cytosolic tail which contains one NADPH binding site, and one FAD binding site (Royer-Pokora *et al.*, 1986; Rotrosen *et al.*, 1992). Thus, gp91phox contains all the elements necessary to transfer electrons from NADPH to oxygen, and is the transfer chain of the enzyme. Electrons transfer is believed to occur in this order:

The NADPH oxidase family has been identified by homology search to gp91phox. The family consists of seven members, five NOXs (NOX-1 to NOX-5) and two DUOXs (DUOX1 and DUOX2), (DUOX for dual oxidase) (Bedard and Krause, 2007). Gp91phox was renamed NOX2 which is also used now to designate the phagocyte NADPH oxidase complex. The new NOX and DUOX are expressed in epithelial cells, endothelial cells, vascular smooth muscle cells, and fibroblast of several tissues such as colon, lung, kidney, heart, and thyroid. ROS production by the NOX/DUOX proteins is very low and is believed to be involved in the regulation of several cellular functions such as local tissue-specific bactericidal activity, vascular tone, thyroid-hormones production, and intracellular signaling (Lambeth, 2007; Dupuy *et al.*, 1991).

Figure 3 Structure of the flavocytochrome b₅₅₈. The flavocytochrome b₅₅₈ is composed of two transmembrane proteins gp91phox (or NOX2) and p22phox. The gp91phox protein has a short N-terminal cytosolic sequence, six transmembrane helices, and one long C-terminal cytosolic tail containing the FAD binding site and one NADPH binding site. The p22phox protein has an N-terminal cytosolic sequence, two transmembrane helices, and one long C-terminal cytosolic tail containing a PRR which binds to p47phox SH3 domains.

p22phox

P22phox also called the α -subunit of the flavocytochrome b₅₅₈, is composed of 195 amino acids and runs at 22 kDa on SDS-PAGE (Parkos *et al.*, 1988). It has two or three predicted transmembrane α -helices and a C-terminal cytosolic tail which contains one proline rich region (PRR) (Pro156-Pro-Arg-Pro159) which binds to p47phox-src homology 3 (SH3) domains during NADPH oxidase activation (de Mendez *et al.*, 1997). Thus, in addition to its electron transfer activity, cytochrome b₅₅₈ is also the central docking site for the cytosolic components. P22phox by associating with its partner gp91phox is essential for the maturation and stabilization of the flavocytochrome b₅₅₈ (DeLeo *et al.*, 2000).

Structure of the Cytosolic Components in Resting Cells

The cytosolic components of phagocyte NADPH oxidase are p47phox, p67phox, p40phox, and a small G protein (rac1 or rac2). In resting cells p47phox, p67phox, and p40phox interact together to form a cytosolic complex (Iyer *et al.*, 1994; Park *et al.*, 1994), while a guanosine diphosphate (GDP) bound Rac1/2 is in a complex with its inhibitor Rho-GDP-dissociation inhibitor (GDI) (Abo *et al.*, 1994). During activation, approximately 10% of these proteins migrate to the plasma

and phagosome membranes to assemble with cytochrome 558 and to induce its activation (Clark *et al.*, 1990; Quinn *et al.*, 1993; El Benna *et al.*, 1994b).

p47phox

P47phox also called NCF1 (neutrophil cytosolic factor 1), is a protein composed of 390 amino acids which migrates at almost 47 kDa on SDS-PAGE (Lomax *et al.*, 1989; Volpp *et al.*, 1989). Its N-terminal amino acid sequence has one PX (phox homology) domain (amino acids 4–121), its middle amino acid sequence contains two SH3 domains (amino acids 159–214 (SH3A) and amino acids 229–284 (SH3B)). The C-terminal sequence is very basic, is rich of serines and arginines and has one region called the autoinhibitory region (AIR) (amino acids 292–340) and a PRR (amino acids 363–368) (Groemping and Rittinger, 2005; El-Benna *et al.*, 2009). In resting cells, some of p47phox may be in a complex with p67phox and p40phox and some is free in the cytosol. In the free form, the two p47phox-SH3 domains interact intramolecularly with the C-terminal region of the non-phosphorylated protein to keep p47phox in an auto-inhibited state (Leto *et al.*, 1994; Sumimoto *et al.*, 1994; Groemping *et al.*, 2003). For this reason the C-terminal region is called the AIR. The X-ray structure of the auto-inhibited form of p47phox (lacking the PX domain) reveals that both SH3 domains form a common interface to create a single shallow groove that constitutes the peptide binding surface (Groemping *et al.*, 2003; Yuzawa *et al.*, 2003; Ogura *et al.*, 2006), thereby acting as a single ‘super’ SH3 domain. In the auto-inhibited form, this site is occupied by the AIR polybasic region of p47phox. Simultaneously, this intramolecular interaction allows the formation of a binding surface on SH3A for the PX domain (Groemping and Rittinger, 2005; Marcoux *et al.*, 2010) to hold the entire multi-domain protein in an inactive conformation. P47phox binds to cytochrome b₅₅₈ during activation. In the activated form the p47phox tandem SH3 domains are occupied by the PRR of the cytoplasmic domain of p22phox instead of the AIR region. The crystal structure of the isolated p47phox-PX domain simultaneously bound to phosphatidylinositol 3,4-bisphosphate and phosphatidic acid revealed that the two lipids bound to two distinct basic pockets in the p47phox domain (Karathanassis *et al.*, 2002) and explained the specificity of this binding (Yaffe, 2002). This study further showed that a point mutation of the second SH3 domain or the phosphorylation of p47phox induced a transition from a closed to an open conformation that binds membranes through the PX domain.

p67phox

P67phox also called NCF2 (Neutrophil Cytosolic Factor 2), is a protein composed of 526 amino acids which migrates at almost 67 kDa on SDS-PAGE (Leto *et al.*, 1990). Its N-terminal amino acid sequence has four tetratricopeptide-rich regions (TPR) (residues (3–36), (37–70), (71–104), (121–154)) that contribute to Rac binding; its middle amino acid sequence contains an activation domain (AD) (residues 199–210), a PRR (residues 226–236), and one SH3 domains (amino acids 243–298(SH3A)) (Han *et al.*, 1998; Yuzawa *et al.*, 2009). The C-terminal sequence has a PB1(phox and Bem1) domain or PC (Phox and Cdc24p) domain (amino acids 351–429) and a second SH3 domain (amino acids 460–514(SH3B)). In resting

cells, all of p67phox is believed to be in a complex with p47phox in the cytosol (Park *et al.*, 1994; Ellson *et al.*, 2001; Kanai *et al.*, 2001). The X-ray structure of full-length p67phox is not known, however, the crystal structure the N-terminal domain in free form and in a complex with Rac–guanosine-5'-triphosphate (GTP) have been described (Lapouge *et al.*, 2000; Grizot *et al.*, 2001a,b). Both studies show that the TPR domains adopt a superhelix fold with a hydrophobic groove ending with a short helix. Recently, structural analysis of p67phox by small angle X-ray scattering (SAXS) has suggested the existence of an intramolecular interaction which might engage the N-terminal SH3 domain (SH3A) and the TPR domains of p67phox (Durand *et al.*, 2010).

p40phox

P40phox also called NCF4 (Neutrophil Cytosolic Factor 4), is a 336-amino-acid protein which migrates at 40 kDa on SDS-PAGE (Wientjes *et al.*, 1993; Tsunawaki *et al.*, 1994). Its N-terminal amino acid sequence has a PX domain (residues 18–136), its middle amino acid sequence contains one SH3 domains (amino acids 173–228) and the C-terminal sequence has a PB1/PC domain (Matute *et al.*, 2005). In resting cells, all of p40phox is in a complex with p67phox in the cytosol. Indeed, it was initially identified through its binding to p67phox. P40phox binding to p67phox strongly stabilizes the protein as its expression is significantly reduced in p67phox deficient CGD patients (Tsunawaki *et al.*, 1994; Kuribayashi *et al.*, 2002). The crystal structure of the full-length p40phox has been described (Honbou *et al.*, 2007). It revealed an intramolecular interaction between the PB1 and the PX domain, however, the interaction interface localizes on the opposite side of that for the p67phox PB1 domain, thus still allowing the PB1–PB1 interaction between p40phox and p67phox. The crystal structure of the p40phox-PX domain bound to phosphatidylinositol 3-phosphate reveals the phospholipid interaction site in p40phox and explained the specificity for 3-phosphoinositide (Bravo *et al.*, 2001; Ellson *et al.*, 2001; Kanai *et al.*, 2001).

Rac

The small GTPase Rac also called (NCF3) is composed of 192 amino acids. In human neutrophils, p21-rac2 is the most abundant rac isoform, but p21-rac1 is also present. However, in monocytes and macrophages Rac1 is the major expressed isoform (Knaus *et al.*, 1991; Abo *et al.*, 1991). Rac1 and Rac2 are 92% identical, they differ by only 14 residues and both can activate the NADPH oxidase. Like cytochrome b₅₅₈, p47phox and p67phox, Rac is essential for optimal NADPH oxidase activation in a cell-free system and in intact neutrophils. In resting cells, all of Rac1 and Rac2 in their GDP-bound form, are in a complex with their natural inhibitor Rho-GDI (Abo *et al.*, 1994; Grizot *et al.*, 2001a,b).

The ‘p47phox–p67phox–p40phox’ complex in resting cells

In the cytosol of resting cells, p47phox, p67phox, and p40phox can associate in a trimer complex with a 1:1:1 stoichiometry (Iyer *et al.*, 1994; Park *et al.*, 1994; Lapouge *et al.*, 2002). However p47phox may exist separately from the p67phox–p40phox dimer complex (Ellson *et al.*, 2001; Kanai *et al.*, 2001). In the complex, p67phox plays a central role as it bridges

Figure 4 Structure of the cytosolic complex. p67phox interacts with p47phox and p40phox. The p47phox PRR interacts with the p67phox-SH3 domain while p40phox interacts with p67phox via a constitutive PB1/PB1 interaction.

Figure 5 Interactions in the assembled NADPH oxidase complex. Activated NADPH oxidase is composed gp91phox, p22phox, p47phox, p67phox, p40phox, and Rac1/2. The p22phox binds to p47phox-SH3 domains. P67phox binds to p47phox, p40phox, Rac, and gp91phox. Rac binds to gp91phox and p67phox. The p47phox- and the p40-phox PX domains interact with membrane phospholipids. p67phox via its AD promotes gp91phox enzymatic activity.

p40phox to p47phox, the PB1 domain of p67phox binds to the PB1 domain of p40phox while the C-terminal SH3 domain of p67phox binds to the PRR of p47phox (Figure 4). As we described above, the free and complexed p47phox is in a closed auto-inhibited state since its AIR (amino acids 292–340) interacts with the two p47phox-SH3 domains to keep p47phox and NOX2 in a resting state which prevents binding of p47phox to p22phox (Groemping *et al.*, 2003).

Assembly and Activation of the NADPH Oxidase Complex

In neutrophils and monocytes, NADPH oxidase activation can be induced by a large number of soluble and particulate agents such as opsonized bacteria, opsonized zymosan, formylated peptides such as formyl-Met-Leu-Phe (fMLF), calcium ionophores (ionomycin, A23187), and the protein kinase C (PKC) activator phorbol myristate acetate (PMA) (El-Benna *et al.*, 2008). These agents induce p47phox

phosphorylation on serines localized in the AIR region and translocation of cytosolic components to the membranes (Figure 5).

NADPH oxidase can be also activated *in vitro* by a mixture of neutrophil cytosol and plasma membranes or the corresponding recombinant proteins in the presence of Mg^{2+} , GTP, and an activating anionic amphiphile such as arachidonate or SDS, which are believed to mimic phosphorylation by providing negative charges (Bromberg and Pick, 1985). This cell-free system can also be activated by protein kinase C instead of anionic amphiphile agents (El-Benna *et al.*, 1995).

Indeed introduction of negative charges by phosphorylation prevents the 'AIR/tandem SH3 domains' interaction and converts p47phox to an open active complex. The tandem SH3 domains then bind the PRR localized in the cytosolic tail of p22phox (Fontayne *et al.*, 2002), while the p47phox PX domain binds to phospholipids in the membranes (Kanai *et al.*, 2001; Ellson *et al.*, 2001) and other p47phox-regions interact

with gp91phox (DeLeo *et al.*, 1995a,b) in order to ensure optimal positioning of the p67phox AD which induces the activation of electron transfer by gp91phox. Indeed p67phox is able to bind gp91phox *in vitro* and p47phox increases this binding (Dang *et al.*, 2001, 2002; Figure 5).

P47phox is the first cytosolic component to interact with cytochrome b₅₅₈ during activation in order to bring the cytosolic complex (p47phox–p67phox–p40phox) to the membrane (Heyworth *et al.*, 1991). Simultaneously, the Rac protein is believed to bind to gp91phox by its Rac insert region (Diebold and Bokoch, 2001) then to p67phox via the TPR domains. These interactions are believed to stimulate electron transfer by gp91phox as does the direct interaction of the AD of p67phox to gp91phox (Han *et al.*, 1998; Dang *et al.*, 2001). The p40phox–PX domain binds also to phospholipids in the membranes in order to stabilize, and localize the assembled complex in internalized phagosomes (Ellson *et al.*, 2001; Kanai *et al.*, 2001; Zhan *et al.*, 2002).

Regulation of NADPH Oxidase Assembly and Activation by Phosphorylation

Phosphorylation of p47phox

Activation of the NADPH oxidase in cells is accompanied by phosphorylation of its cytosolic subunits p47phox, p67phox, and p40phox (El Benna *et al.*, 1994a; El-Benna *et al.*, 1997; Bouin *et al.*, 1998) and also its membrane subunits p22phox and gp91phox (Regier *et al.*, 1999; Raad *et al.*, 2009). However, only the role of p47phox phosphorylation is extensively studied (El-Benna *et al.*, 2009). Indeed, p47phox was first identified because its phosphorylated form was missing in neutrophils isolated from some CGD-patients (Segal *et al.*, 1985). In resting cells, p47phox is not phosphorylated, in stimulated cells eight to nine p47phox isoforms were seen due to its phosphorylation (Rotrosen and Leto, 1990). Phosphorylation analysis showed that p47phox is phosphorylated on multiple sites in the C-terminal portion of the protein, including serines 303 to 379 (El Benna *et al.*, 1994a,1996). Combined mutation of all these serines was used to show that p47phox phosphorylation is required for NADPH oxidase activation in intact cells (Faust *et al.*, 1995; Belambri *et al.*, 2012). Individual mutation of each serine showed that only serine 379 was important for oxidase activation (Faust *et al.*, 1995). Double mutation analysis showed that two pairs of phosphorylated serines, Ser(303 + 304) and Ser(359 + 370), are necessary for NADPH oxidase activation (Johnson *et al.*, 1998; Inanami *et al.*, 1998).

The ‘phosphorylated–p47phox–Pin1’ axis

Phosphorylation of p47phox or anionic amphiphiles that mimics phosphorylation, induce a conformational changes of the protein that prevent the interaction between the AIR and the SH3 domains (Fontayne *et al.*, 2002; Huang and Kleinberg, 1999). This open-p47phox state initiates assembly of the active enzyme via interaction of the SH3 domains with the PRR of p22phox. Phosphorylated p47phox also increases the interaction between p67phox and gp91phox (Dang *et al.*, 2002). Most of these results were obtained in a cell free system with recombinant p47phox which was heavily phosphorylated

in vitro by PKC (Fontayne *et al.*, 2002). In the context of intact neutrophils, NOX2 hyper-activation occurs when cells encounter first a priming agent then the stimulating agent. We have shown that the proline isomerase Pin1 is likely to be a major enzyme involved in NOX2 hyperactivation through the regulation of p47phox hyper-phosphorylation (Boussetta *et al.*, 2010). Indeed, the pro-inflammatory cytokine tumor necrosis factor- α (TNF α), does not activate NADPH oxidase but primes its activation in response to secondary stimulus such as N-Formyl-Met-Leu-Phe (FMLP) (El-Benna *et al.*, 2008; Brown *et al.*, 2004). This phenomenon is critical in the physiological regulation of microbicidal activity and during tissue injury in inflammatory diseases (Condliffe *et al.*, 1998; El-Benna *et al.*, 2008). TNF α induces partial phosphorylation of p47phox on Ser345 and this mechanism is critical for the priming of ROS production in neutrophils (Dang *et al.*, 2006). TNF α also induced the activation of the proline isomerase Pin1 followed by its binding to p47phox, only when this last one is phosphorylated on Ser-345. Pin1 then catalyzed a conformational change of p47phox that facilitate subsequent phosphorylation of the protein on other sites by PKC and consequently allowed NOX2 hyperactivation (Boussetta *et al.*, 2010). Thus the ‘p47phox–Ser345 phosphorylation–Pin1’ axis controls TNF α -induced NADPH oxidase hyperactivation in human neutrophils. This pathway was also involved in TLR7/8-mediated neutrophil NADPH oxidase priming (Makni-Maalej *et al.*, 2012).

Phosphorylation of p67phox and p40phox

The p67phox is also phosphorylated in human neutrophils, although at lower level than p47phox (El-Benna *et al.*, 1997). P67phox is constitutively phosphorylated in resting human neutrophils, a process that can be enhanced by stimulation of cells (Dang *et al.*, 2011). This phosphorylation occurs on serine and threonine residues (El-Benna *et al.*, 1997; Forbes *et al.*, 1999). Several protein kinases such as PKC, ERK1/2, and p38MAPK can phosphorylate p67phox (Dang *et al.*, 2003). Up until now one p67phox phosphorylated site corresponding to threonine 233 has been identified (Forbes *et al.*, 1999), however, phosphorylation of other sites has not been entirely ruled out. Interestingly phosphorylation studies have suggested that p67phox may exist in an auto-inhibited state (Dang *et al.*, 2003). Indeed cryptic phosphorylation sites localized in the C-terminal portion of p67phox become accessible to ERK2 only after the removal of the N-terminal fragment of the protein. Furthermore, the addition of the N-terminal fragment inhibited the phosphorylation reaction (Dang *et al.*, 2003). The presence of the intramolecular interaction in p67phox was also suggested by the SAXS analysis of p67phox (Durand *et al.*, 2010). Phosphorylation of p67phox does not affect its binding to gp91phox *in vitro*. Its role can be further investigated by the identification of all the phosphorylated sites and site directed mutagenesis.

P40phox is also phosphorylated in neutrophils and neutrophil-like HL-60 cells. It is phosphorylated on two major sites Thr154 and Ser315 (Bouin *et al.*, 1998). Mutation of these residues did not affect the interaction with p67phox and p47phox in the two hybrid system (Bouin *et al.*, 1998). However, it was shown that phosphorylated p40phox increased the binding of p67phox to cytochrome b₅₅₈ (Dang *et al.*, 2002). In another study, the addition of phosphorylated

p40phox in a PKC-activated cell-free system inhibited NADPH oxidase activation (Lopes *et al.*, 2004). It was suggested that phosphorylation of Thr154 could induce a conformational changes that induce an inhibitory form of p40phox. However, recent studies using wild type and mutated version of p40phox introduced into fully differentiated mouse neutrophils by retroviral transduction of p40phox $-/-$ bone marrow progenitors has shown that phosphorylation of threonine 154 in p40phox is an important new element in the physiological activation of NOX2 (Chessa *et al.*, 2010) that remains to be further explored.

Phosphorylation of gp91phox and p22phox

Gp91phox/NOX2 is phosphorylated in human neutrophils activated by several agents known to induce NADPH oxidase activation (PMA, fMLP, and opsonized zymosan) (Raad *et al.*, 2009). In addition, this phosphorylation occurs in the C-terminal region containing the flavoprotein domain. PKC phosphorylation increased electron transfer activity of the gp91phox flavoprotein cytosolic domain and its binding to Rac2, p67phox, and p47phox (Raad *et al.*, 2009). These data suggest that phosphorylation of gp91phox could play a stimulatory role for NADPH oxidase. The p22phox subunit is phosphorylated in stimulated human neutrophils (Regier *et al.*, 1999). The major p22phox phosphorylated site was identified as Thr147 (Lewis *et al.*, 2010). Mutation of this site to Ala induced inhibition of NADPH oxidase activation and p22phox/p47phox interaction. These results indicate that phosphorylation of p22phox on Thr147 is critical for complex assembly and activation.

Conclusion

ROS production by the phagocyte NOX2 is essential for host defense against invading pathogens. However, its hyperactivation can induce tissue injury involved in inflammatory disease. This multicomponent enzyme is tightly regulated to ensure activation when required, and deactivation to limit excessive ROS production. The subunits of this multicomponent enzyme are today fully identified. At the exception of the Rac protein and p40phox, only the structure of some domains of the other subunits have been described. Some of the signaling pathways have been identified. Future studies are required to determine the structure of full-length gp91phox, p22phox, p47phox, and p67phox, and the assembled complex, the role of the phosphorylation of p67phox, p40phox, and gp91phox, the regulation of the activation/deactivation in intact cells, the signaling pathways that control the relative amounts of intracellular versus extracellular ROS, and the identification of novel specific inhibitors for anti-inflammatory therapeutic purposes.

Introduction

The vertebrate immune system is composed of two major subdivisions, the innate or inborn immune system and the adaptive or acquired immune system. The innate immune system is our first line of defense against pathogens, has anatomical features that serve as barriers to infection (such as the skin and epithelia or mucous membranes lining the respiratory, gastrointestinal, and urinary tracts) and includes defenses that are constitutively present and ready to be deployed upon infection. The adaptive immune system on the other hand is antigen specific and confers protection against reexposure to the same pathogen. Cells of the innate immune system such as epithelial cells, macrophages, neutrophils, and dendritic cells (DCs) detect pathogens by employing a network of germline-encoded sensors that are present on the cell surface or in the cytoplasm. These are collectively called pattern recognition receptors (PRRs) to denote their ability to recognize conserved microbial structures or pathogen-associated molecular patterns (PAMPs). While evolutionarily believed to sense ligands of microbial origin, some PRRs can also detect endogenous danger signals released from damaged tissues (danger-associated molecular patterns; DAMPs). The major classes of innate sensors include Toll-like receptors (TLRs), nucleotide oligomerization domain leucine-rich repeat receptors (NLRs), C-type lectin receptors (CLRs), retinoic acid-inducible gene I-like receptors (RLRs), as well as several putative sensors of intracellular DNA such as absent in melanoma 2 (AIM2), stimulator of interferon genes (STING) and DNA-dependent activator of interferon regulatory factors (DAI) (Ishii *et al.*, 2008). Upon activation by PAMPs or DAMPs, PRRs initiate innate immune activities and instruct subsequent adaptive immune responses, enabling both short-term effector function as well as long-lasting immunological memory. The PAMPs recognized and the subsequent immune responses initiated vary depending upon the invading microbe and the PRR triggered; however signaling generally converges on activation of nuclear transcription factors such as nuclear factor- κ B (NF- κ B) and interferon regulatory factors (IRFs) leading to pro-inflammatory cytokine production, or formation of oligomeric signaling complexes called inflammasomes that activate caspase-1 leading to generation of bioactive interleukin (IL)-1 β , IL-18 and pyroptosis. Exquisite coordination of several innate immune pathways determines the quality, magnitude, and duration of the ensuing host response, ultimately leading to containment of invading microorganisms. Apart from its well appreciated role in host defense, innate signaling is also emerging as a critical factor in human inflammatory disease. Indeed, the unrestrained inflammatory response propagated by innate sensors can be detrimental and has been implicated in the development of a variety of immune disorders including atherosclerosis, Type 1 diabetes, inflammatory bowel disease, and systemic lupus erythematosus (SLE) (Li *et al.*, 2009; Holm *et al.*, 2013; Zhong *et al.*, 2013). In this article we review

current information on innate immune signaling with a focus on cytoplasmic sensing. In 'Classes, Structure, and Activation of Innate Sensors,' we introduce the major classes of innate sensors, their signaling pathways and role in mediating protective host defense and/or autoimmunity. In 'Role of Intracellular Organelles and Spatial Relocation,' we discuss the role of subcellular structures and spatial patterns of intracellular movement in generation and/or propagation of the innate immune response. In 'Combinatorial Sensing and PRR Crosstalk,' we discuss the crosstalk between different PRR pathways and integration of signals from multiple ligands displayed by a microbe. A holistic and predictive understanding of innate immunity requires systems-level integration of information from multiple molecular levels, an aspect that is discussed in 'Multiscale Regulation of Cytosolic Sensing Pathways.'

Classes, Structure, and Activation of Innate Sensors

CLRs

CLRs are a large, functionally diverse group of soluble and transmembrane proteins that are primarily involved in detecting a wide range of carbohydrate structures on fungal pathogens, but can also recognize a diverse repertoire of structurally dissimilar microbe-associated or endogenous ligands (Hoving *et al.*, 2014). CLRs are characterized by a C-type lectin domain (CTLN) also referred to as a carbohydrate recognition domain (CRD) in cases where carbohydrates are recognized (Figure 1). The CLR family encompasses more than 1000 identified members with diverse functions including endocytosis, phagocytosis, cell adhesion, complement activation, tissue remodeling, antimicrobial, pro-inflammatory, and anti-inflammatory responses. However, based on their molecular structure CLRs can be classified into three notable groups: two groups of membrane-bound CLRs namely Type I CLRs that contain multiple CRDs, and Type II CLRs that contain a single CRD, and a group of soluble CLRs (Table 1). Prominent examples of CLRs from these groups include dectin-1, dectin-2, DC-specific ICAM3-grabbing nonintegrin (DC-SIGN), mincle, DNGR-1 (CLEC9A), and mannose-binding lectin (MBL). CLRs may be activatory or inhibitory based upon their ability to associate with signaling molecules or the presence of specific motifs in their cytoplasmic tails, which can be one of at least four different types: immunoreceptor tyrosine-based activation motifs (ITAMs), immunoreceptor tyrosine-based inhibitory motifs (ITIMs), a single tyrosine-based motif (hemiITAM), or tyrosine-independent motif. Upon ligand binding of activatory CLRs, the tyrosine residues of an ITAM are phosphorylated by Src family kinases which in turn promote the recruitment of Syk family kinases culminating in the activation of various cellular responses, notably the activation of NF- κ B and production of reactive oxygen species (ROS).

Figure 1 Chart showing the major classes of innate immune sensors, their general domain organization, and adaptors utilized for signaling. These include the TLRs, NLRs, RLRs, and ALRs. In the case of NLRs, the N-terminal effector region can be a caspase activation and recruitment domain (CARD), pyrin domain (PYD), baculoviral inhibitor of apoptosis repeat (BIR), or transactivator domain (AD) depending upon the NLR. ALR, AIM2-like receptor; ASC, Apoptosis-associated speck-like protein containing CARD; CLR, C-type lectin receptor; CTD, C-terminal domain; CTLD, C-type lectin domain (CTLD); DD, death domain; HIN, hematopoietic expression; interferon-inducible nature; and nuclear localization; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; LRR, Leucine-rich repeats; MAL, MYD88-adaptor-like protein; MAVS, mitochondrial antiviral signaling protein; MYD88, myeloid differentiation primary-response protein 88; NLR, NOD-like receptor; NOD, Nucleotide-binding oligomerization domain; RIPK2, receptor-interacting serine/threonine kinase 2; RLR, RIG-I-like receptor; Syk, Spleen tyrosine kinase; TIR, Toll/interleukin-1 receptor; TLR, Toll-like receptor; TRAM, TRIF-related adaptor molecule; TRIF, TIR domain-containing adaptor protein inducing interferon- β .

Table 1 Summary of select CLRs, their ligands and responses

Type	Sensor	Ligand(s)	Response
Type I	DEC 205	CpG oligonucleotides, ligands expressed by dying apoptotic or necrotic cells	Antigen presentation, cytokine production
	MMR	Mannose, <i>N</i> -acetylglucosamines, fucose residues <i>Pneumocystis carinii</i> , <i>Leishmania donovani</i>	Phagocytosis, cytokine production, IL-8 in cooperation with TLR2
Type II	Dectin-1	β -glucans	Phagocytosis, ROS production, activation of NF- κ B and AP-1 through SYK adaptor, ROS production and potassium efflux resulting in NLRP3 inflammasome activation
	Dectin-2	High mannose-type carbohydrates	
	Mincle	Fungal α -mannose, mycobacterial glycolipid trehalose-6'-6'-dimycolate	Activation of NF- κ B and AP-1 through the Fc receptor common γ -chain (FcR γ) and SYK
	DC-SIGN	Human immunodeficiency virus (HIV)-1, Hepatitis C virus, dengue virus, cytomegalovirus, ebola virus, <i>Leishmania</i> , and <i>Candida</i> species	Modulation of TLR signaling by acetylation of active NF- κ B p65 through the serine threonine kinase Raf-1 resulting in anti-inflammatory responses
	CLEC9A	DAMPs such as exposed actin filaments of damaged or dead cells	Antigen presentation
Soluble	MBL	Repetitive mannose and/or <i>N</i> -acetylglucosamine residues, including those on HIV	Phagocytosis, anti-inflammatory cytokines

Ligand engagement of inhibitory CLRs commonly results in ITIM tyrosine phosphorylation by Src kinases, the recruitment and activation of protein tyrosine phosphatases such as SHP-1 and SHP-2 and the dephosphorylation of substrates leading to

the inhibition of cellular activation (Osorio *et al.*, 2011; Redelinghuys and Brown, 2011). CLRs have been well-reviewed elsewhere (Hoving *et al.*, 2014; Osorio *et al.*, 2011) and because they primarily function in recognition of extracellular ligands,

will not be covered in detail in this review. A summary of select CLRs, including their known ligands and signaling responses, is shown in [Table 1](#).

TLRs

TLRs were the first class of innate sensors to be identified and are the most well characterized PRRs. To date, 13 members of the TLR family have been identified in mammals. These recognize a wide range of PAMPs including LPS (recognized by TLR4); bacterial peptidoglycan, lipoproteins, and fungal zymosan (recognized by TLR2-TLR1 or TLR2-TLR6 heterodimers); bacterial flagellin (recognized by TLR5); unmethylated bacterial or viral CpG DNA (recognized by TLR9); viral single-stranded RNA (recognized by TLR7 and TLR8) and viral double-stranded RNA (recognized by TLR3); and bacterial 23S ribosomal RNA (recognized by TLR13) ([Table 2](#); [Akira et al., 2006](#); [Kawai and Akira, 2011](#)). TLRs are type I transmembrane proteins characterized by three distinct domains: an extracellular ligand sensing domain-containing varying numbers of leucine-rich repeat (LRR) motifs that mediate the recognition of PAMPs, a transmembrane region, and a cytoplasmic domain homologous to that of the interleukin 1 receptor (IL-1R), termed the Toll/IL-1R homology (TIR) domain that activates downstream signaling pathways ([Figure 1](#)).

TLRs are expressed on myeloid and lymphoid cells of hematopoietic origin, including macrophages, DCs, B cells, specific types of T cells, and even on non-hematopoietic cells such as fibroblasts and epithelial cells. Moreover, TLRs may be expressed extra- or intracellularly depending upon their PAMP recognition properties. While certain TLRs (TLRs 1, 2, 4, 5, and 6) are expressed and bind to their respective ligands on the cell surface, others (TLRs 3, 7, 8, 9, and 13) are found almost exclusively in intracellular compartments such as endosomes where they sense microbial and host-derived nucleic acids ([O'Neill et al., 2013](#); [Blasius and Beutler, 2010](#)). TLRs 11 and 12 also localize within endosomal compartments where they are involved in the detection of *Toxoplasma gondii* profilin protein ([Yarovinsky, 2014](#); [Andrade et al., 2013](#); [Pifer et al., 2011](#)). All the TLRs are expressed in mice; however, humans lack functional TLR11, TLR12, and TLR13 genes.

TLR signaling is initiated by ligand-induced homo-dimerization or heterodimerization of receptors. Following dimerization, the TIR domains of TLRs associate with TIR domain-containing adaptor proteins, either myeloid differentiation primary-response protein 88 (MYD88), and MYD88-adaptor-like protein (MAL) also called TIR domain-containing adaptor protein (TIRAP), or TIR domain-containing adaptor protein inducing IFN β (TRIF) and TRIF-related adaptor molecule (TRAM). Engagement of these adaptor molecules

Table 2 Summary of human and mouse TLR ligands, adaptors, responses, and associated human diseases

Sensor	Ligand(s)	Adaptor	Response	Associated diseases
TLR 1/TLR2	Triacyl lipopeptides (Pam3CSK4)	MyD88 TIRAP/MAL	Inflammatory cytokines	
TLR 2/TLR6	Diacyl lipopeptides Lipoteichoic acid Zymosan Glycolipids GPI anchor Phospholipomannan	MyD88 TIRAP/MAL	Inflammatory cytokines Type 1 IFN	Atherosclerosis
TLR 3	Synthetic dsRNA Viral dsRNA	TRIF	Type I IFN	Virus-triggered autoimmune disease
TLR 4	LPS Mannan Glucuronoxylomannan Glycoinositolphospholipids GPI anchor	MyD88 TIRAP/MAL TRAM TRIF	Inflammatory cytokines Type 1 IFN	Atherosclerosis
TLR 5	Flagellin	MyD88 TRIF	Inflammatory cytokines	
TLR 7	ssRNA imidazoquinoline derivatives (R848)	MyD88	Inflammatory cytokines Type 1 IFN	Psoriasis, multiple sclerosis, systemic lupus erythematosus
TLR 8	ssRNA imidazoquinoline derivatives (R848)	MyD88		Multiple sclerosis
TLR 9	Unmethylated CpG DNA Synthetic CpG oligodinucleotides Hemozoin	MyD88	Inflammatory cytokines Type 1 IFN	Psoriasis, systemic lupus erythematosus
TLR 10 (humans)	Unknown	MyD88	Activation of NF- κ B and ENA-789 promoters	
TLR11	<i>Toxoplasma gondii</i> profilin protein, uropathogenic <i>Escherichia coli</i> , <i>Salmonella</i> flagellin	MyD88	NF- κ B and IRF8 dependent IL-12 production	
TLR12	<i>T. gondii</i> profilin protein	MyD88	NF- κ B and IRF8 dependent IL-12 production	
TLR13	Bacterial 23S ribosomal RNA	MyD88	Activation of NF- κ B	

organizes downstream signaling that involves interactions between IL-1R-associated kinases (IRAKs) and the TNF receptor-associated factors (TRAFs), leading to the activation of the mitogen-activated protein kinases (MAPKs), JUN N-terminal kinase (JNK), p38, and to the activation of transcription factors (Figure 2). Two important families of transcription factors that are activated downstream of TLR signaling are NF- κ B and the IRFs, but other transcription factors, such as cyclic AMP-responsive element-binding protein (CREB) and activator protein 1 (AP1) may also be activated. A major consequence of TLR signaling is the induction of pro-inflammatory cytokines such as tumor necrosis factor α (TNF- α), IL-1, IL-6, and IL-12, and in the case of the endosomal TLRs, the induction of type 1 interferon (IFN) (Figure 2; Blasius and Beutler, 2010; O'Neill *et al.*, 2013).

Activation of TLRs on antigen-presenting cells such as macrophages, DCs and B cells, strongly influences the development of adaptive immune responses by controlling several essential processes such as the upregulation of co-stimulatory or accessory molecules like CD80 and CD86, enhancement of antigen presentation, B-cell proliferation and maturation, activation of T cells, and suppression of regulatory T cell activity (Iwasaki and Medzhitov, 2010), thereby mediating effective host defense to a wide range of pathogens. However, an unchecked TLR-induced inflammatory response can be deleterious to the host resulting in a variety of immune disorders. TLRs are implicated in the pathogenesis of autoimmune diseases, such as SLE, rheumatoid arthritis, atherosclerosis, hepatitis, diabetes, kidney disease, and certain other disorders (Li *et al.*, 2009). Recent studies have shown that functional TLRs are expressed not only on immune cells, but also on cancer cells, implicating a role of TLRs in tumor biology. Analogous to their favorable and detrimental roles in inflammation, increasing evidence suggests that TLRs act as a double-edged sword in cancer cells too, pointing to a dual function of TLRs as anti- and pro-tumor modulators (Basith *et al.*, 2012). While unrestrained TLR signaling provides a microenvironment conducive for tumor growth and evasion of the immune response, TLRs can also trigger an antitumor response that inhibits tumor progression and promotes tumor clearance. Thus, apart from their protective role against various pathogens, the involvement of TLRs in autoimmune diseases and tumorigenesis indicates the need for further studies to delve into the potential of targeting TLR signaling for therapeutic benefit under these conditions.

NLRs

While TLRs detect microbial signatures in the extracellular environment or intracellularly in the lumen of endosomes, NLRs are the largest known family of innate sensors that survey the cytosolic environment. In humans, 23 NLRs have been identified (Harton *et al.*, 2002; Inohara and Nunez, 2003; Table 3). Their structural hallmark is a modular organization of three domains with distinct function: a variable C-terminal LRR domain for ligand binding, a conserved nucleotide binding or oligomerization domain (NBD or NOD), and a variable N-terminal effector or protein interaction domain that mediates downstream signaling cascades (Figure 1). The N-terminal domain mediates homotypic protein-protein interactions and can be one of four different types depending upon the receptor subclass: NLRA or Class II transactivator (CIITA) contains an acidic transactivation domain, NLRBs or neuronal apoptosis inhibitor proteins (NAIPs) contain a baculoviral inhibitor of apoptosis repeat (BIR) domain, NLRs have a caspase activation and recruitment domain (CARD), and NLRPs possess a pyrin domain (PYD). The NLRX1 effector domain bears no homology to the N-terminal region of any of the above four subclasses and is instead categorized as a CARD-related X effector domain. PAMPs and DAMPs are believed to be sensed by the C-terminal LRR domain. Upon ligand binding, the auto-inhibitory LRR undergoes a conformational change, allowing for protein oligomerization through the central NOD domain. This in turn exposes the N-terminal effector domain, allowing for recruitment of downstream signaling adaptors and effector proteins resulting in formation of an oligomeric complex. The activating stimuli, mechanisms of activation, and response to ligand sensing vary within the NLR family (Table 3) and have been well defined only for a few family members; the physiologic functions and relevant signaling pathways of most members of the NLR family are either unknown or poorly defined. Among the NLRs that have been studied intensively, NLRP3, NLRP1, and NLRC4 form a macromolecular signaling complex called the inflammasome that acts as a scaffold for activation of caspase-1, a key step that leads to processing and secretion of the potent pro-inflammatory cytokines IL-1 β and IL-18, while NOD1 and NOD2 form signaling platforms that activate NF- κ B (Martinon *et al.*, 2009).

Figure 2 Overview of cytoplasmic innate sensing and signaling mechanisms. Major signaling cascades triggered by extracellular and intracellular PRRs are shown. Pathogen- or danger-associated stimuli are detected by innate sensors (1), often through combinatorial sensing in which multiple receptors sense ligands from the same microbe. Ligand binding results in conformational changes, followed by self-association and/or autophosphorylation of the receptors, allowing them to bind adaptor proteins. Additional trafficking proteins (not depicted) may guide the active oligomeric complexes to secondary compartments within the cell (2). For instance, TLR4 may be trafficked to early endosomal compartments where it binds the adaptors TRIF and TRAM. Activated RIG-I and NLRP3 associate with MAVS on the mitochondrial surface; RIG-I may additionally associate with MAVS on the peroxisomes. STING moves from the ER to a secondary structure that has, as yet, not been fully identified and is therefore depicted with a '?'. Adaptor proteins may allow for assembly of large, oligomeric, multiprotein signaling complexes capable of activating downstream mediators and transcription factors (TFs) resulting in a functional response (3). For example, activated NLRP3 and AIM2 form structures called inflammasomes that serve as platforms for activation of caspase-1, which in turn cleaves pro-IL-1 β and pro-IL-18 to produce active cytokines. Activated RIG-I induces polymerization of MAVS into large self-propagating prion-like structures that trigger phosphorylation cascades ultimately leading to activation of the TFs IRF3 and IRF7. The nature of RIG-I and MDA5 interactions with adaptor proteins on the peroxisome is not yet fully understood and is therefore depicted with a '?'. IRF3 and IRF7 translocate to the nucleus and initiate transcription of type 1 IFN (4). The TF NF- κ B is also activated by RIG-I-MAVS interaction, ultimately leading to transcription of a number of pro-inflammatory cytokines. Combinatorial sensing of diverse ligands can result in simultaneous or sequential activation of multiple pathways, which may be important for generating a tailored, specific response to a potential pathogen.

Table 3 Summary of human NLRs, their activators, responses, and associated diseases

Effector domain	Sensor	Activator(s)	Response	Associated diseases
CARD	CIITA	Unknown	MHC class II transcriptional activation	Bone density defects, Hodgkin's lymphoma, B-cell lymphoma, celiac disease, arthritis, multiple sclerosis, primary adrenal insufficiency, systemic lupus erythematosus, diabetes
	NOD1	Meso-diaminopimelic acid (DAP), γ -D-glutamyl-meso-diaminopimelic acid (iE-DAP), meso-lanthionine, GM-tripeptide, FK156, FK565	NF- κ B activation through IKK complex; MAP kinase pathway activation leading to pro-inflammatory responses	Inflammatory bowel disease, atopic eczema, asthma
	NOD2	Muramyl dipeptide (MDP), M-TR _{LVS}	NF- κ B activation through IKK complex; MAP kinase pathway activation leading to pro-inflammatory responses	GVHD, Blau disease, Crohn's disease, asthma, atopic dermatitis, arthritis, sarcoidosis, prostate and endometrial cancer, gastric lymphoma, leprosy
	NLRC4	Flagellin, Type III secretion system components	Inflammasome formation resulting in caspase-1 activation and cleavage of IL-1 β and IL-18 to their active forms	Susceptibility to bacterial infections
	NLRC3	Unknown	Negative regulator of T cell activation, TLR, and STING signaling	
	NLRC5	Unknown; NLRP3 agonists, including bacterial PAMPs and crystals have been reported as elicitors in cell culture systems	Transcriptional regulator of MHC class I. Other functions are not fully understood because response appears to vary with species, context, and cell type	Susceptibility to viral infections
	NLRX1	Unknown	Activates NF- κ B and ROS through JNK pathway, negatively regulates RIG-I-mediated IFN response and LPS-elicited TRAF6-IKK signaling pathways	Susceptibility to chronic hepatitis B infection, gastric cancer
PYD	NLRP1	Muramyl dipeptide, <i>Bacillus anthracis</i> lethal toxin	Inflammasome assembly resulting in caspase-1 activation and production of active IL-1 β and IL-18	Skin autoimmune disorders, vitiligo, Addison's disease, diabetes, celiac disease, autoimmune thyroid disorders, systemic lupus erythematosus, systemic sclerosis, giant cell arteritis, congenital toxoplasmosis, Alzheimer's disease, corneal intraepithelial dyskeratosis, arthritis
	NLRP2	Unknown		Beckwith–Wiedemann syndrome, GVHD
	NLRP3	Crystals (monosodium urate, calcium pyrophosphate dihydrate, cholesterol, asbestos, silica, hydroxyapatite), amyloid β , mitochondrial DNA, cardiolipin, ceramides, ATP, ROS, RNA viruses, bacterial toxins	Inflammasome assembly resulting in caspase-1 activation and production of active IL-1 β and IL-18	Gout, Cryopyrin-associated periodic fever syndromes (CAPS), diabetes, celiac disease, psoriasis, inflammatory bowel diseases, Alzheimer's disease, atherosclerosis
	NLRP4	Unknown	Unknown, possible suppressor of NF- κ B	
	NLRP5	Unknown	Unknown	Familial biparental hydatidiform moles

(Continued)

Table 3 Continued

Effector domain	Sensor	Activator(s)	Response	Associated diseases
	NLRP6	Unknown	Unknown, possible negative regulator of NF- κ B and IL-1 β , an NLRP6 inflammasome has been proposed in mouse colonic epithelial cells	Metabolic syndrome-associated abnormalities, colitis, and colon cancer
	NLRP7	Bacterial acylated lipoproteins (acLP)	Unknown, possible negative regulator of IL-1 β , inflammasome assembly in response to bacterial acLP	Familial biparental hydatidiform moles, abnormal pregnancies and embryonic development, testicular and endometrial cancer
	NLRP8	Unknown	Unknown	Alzheimer's disease, colorectal cancer
	NLRP9	Unknown	Unknown	Abnormal embryonic development
	NLRP10	Unknown	Negatively regulates caspase-1 activation, regulation of DC emigration from inflamed tissues in mice	Atopic dermatitis
	NLRP11	Unknown	Unknown	
	NLRP12	Unknown	Negatively regulates NF- κ B activation	Hereditary fever syndromes, dermatitis
	NLRP13	Unknown	Unknown	Abnormal embryonic development
	NLRP14	Unknown	Unknown	Familial biparental hydatidiform moles, spermatogenic failure
BIR	NAIP	Type III secretion system needle proteins	Formation of a large oligomeric complex with NLRC4 resulting in caspase-1 activation and production of IL-1 β	Spinal muscle atrophy

The current paradigm for NLR activation is self-oligomerization followed by recruitment of adaptor proteins that mediate activation of downstream effectors. In the case of NOD1 and NOD2, two well-studied NLRs that sense different components of peptidoglycan from Gram-negative and Gram-positive bacteria (Elinav *et al.*, 2011), ligand binding allows for the recruitment of the receptor-interacting serine-threonine kinase 2 (RIPK2) adaptor protein through the exposed CARD subsequently leading to polyubiquitination of the inhibitor of NF- κ B kinase subunit gamma (IKK γ). This in turn culminates in activation of the I κ B kinase (IKK) complex, I κ B α phosphorylation followed by its degradation and activation of NF- κ B (Windheim *et al.*, 2007; Abbott *et al.*, 2007; Figure 2). NOD1 or NOD2 activation also results in the activation of MAP kinases such as ERK-1, ERK-2, JNK, and p38, which coordinate with NF- κ B to upregulate the expression of pro-inflammatory molecules (Girardin *et al.*, 2001; Pauleau and Murray, 2003; Park *et al.*, 2007). In addition, activation of NOD2 by single-stranded viral RNA from respiratory syncytial virus (RSV), vesicular stomatitis virus (VSV), and influenza virus has been shown to trigger a noncanonical signaling pathway that requires the mitochondrial antiviral signaling protein (MAVS) and induces IRF3 activity, leading to the production of type 1 IFN (Sabbah *et al.*, 2009). In the case of NLRP3, conformational changes in the molecule following ligand sensing expose the PYD domain resulting in interaction with a similar domain on the adaptor protein apoptosis-associated speck-like protein containing a CARD (ASC), which through homotypic CARD domain interactions associates with

procaspase-1 resulting in its auto-catalytic cleavage to enzymatically active caspase-1 (Agostini *et al.*, 2004). The latter then cleaves the pro forms of IL-1 β and IL-18 to produce active cytokine. This process is amplified by a second adaptor protein MAVS in response to noncrystalline NLRP3 activators like poly I:C (Subramanian *et al.*, 2013). In contrast to NLRP3, NLRP1, and NLRC4 contain a CARD domain that allows them to associate directly with procaspase-1. NLRC4 and NLRP1 may also recruit ASC, resulting in augmented inflammasome activity; however ASC is not absolutely required for inflammasome assembly (Lamkanfi and Dixit, 2014; Schroder and Tschopp, 2010; Hsu *et al.*, 2008).

Among the inflammasome-forming NLRs, NLRP3 is perhaps the best studied. NLRP3 inflammasome formation appears to require at least two distinct signals. The first signal is an NF- κ B activating stimulus, which leads to transcriptional upregulation of pro-IL-1 β and NLRP3. This is often referred to as a 'priming' signal and may consist of a TLR activator such as LPS (Bauernfeind *et al.*, 2009). A second signal then activates NLRP3 resulting in inflammasome assembly (Lamkanfi and Dixit, 2014). The nature of this activating stimulus can be diverse. A variety of signals associated with infection or metabolic dysfunction can activate NLRP3, ranging from crystalline substances like monosodium urate, cholesterol, calcium pyrophosphate dehydrate, silica or alum crystals, to noncrystalline activators such as RNA or bacterial toxins, and endogenous danger signals like ATP, mitochondrial DNA, cardiolipin, ceramides, low cytosolic potassium, and increased intracellular calcium (Dostert *et al.*, 2008; Cassel *et al.*, 2008;

Cruz *et al.*, 2007; Lee *et al.*, 2012). How these chemically and structurally distinct stimuli elicit a response from a single sensor is unclear (Gross *et al.*, 2011). One proposed common feature of NLRP3 activators is induction of ROS that may lead to the generation of a potential ligand of NLRP3 or may modify NLRP3 or associated proteins directly (Cruz *et al.*, 2007; Zhou *et al.*, 2010). However, a study also argues that ROS are required for transcriptional induction of NLRP3 expression, but not for NLRP3 activation (Bauernfeind *et al.*, 2011); these divergent conclusions may be due to potentially off-target effects of pharmacological scavengers or inducers of ROS, and their usage at differing doses or duration that may cause varying outcomes depending on the cell type. Another reported pathway involves lysosome disruption by crystals such as those formed by cholesterol, uric acid, or alum, causing release of active cathepsin B that presumably acts as an upstream activator of NLRP3 (Hornung *et al.*, 2008). Interestingly, deubiquitination of NLRP3 can prime NLRP3 non-transcriptionally and is essential for ASC aggregation and inflammasome activity, however the precise purpose of this deubiquitination is not known (Juliana *et al.*, 2012; Lopez-Castejon *et al.*, 2013). The high level of regulation of the NLRP3 inflammasome may be due in part to the prion-like nature of NLRP3 inflammasome assembly. Nucleation of ASC oligomerization through the PYD has been shown to promote energetically-favorable polymerization into large, stable, amyloid-like structures which may serve to quickly amplify signaling (Cai *et al.*, 2014), yet which may be difficult for the cell to reverse once initiated.

The NLRC4 inflammasome has mainly been implicated in the host defense to bacterial pathogens such as *Salmonella typhimurium*, *Legionella pneumophila*, *Burkholderia pseudomallei*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* (Corridoni *et al.*, 2014). Posttranslational phosphorylation of Ser533 in NLRC4 by PKC δ has been proposed to be crucial for NLRC4 inflammasome function (Qu *et al.*, 2012). NLRC4 is expressed mostly on myeloid cells and activates caspase-1 dependent production of bioactive IL-1 β upon cytosolic detection of bacterial flagellin, and components of the type III secretion system (T3SS) (Miao *et al.*, 2006, 2010b; Franchi *et al.*, 2006). These bacterial ligands trigger oligomerization of NLRC4 with NAIPs, which have been identified as critical components of the NLRC4 inflammasome. In mice, NAIP5 and NAIP6 in complex with NLRC4 confer specificity for recognition of bacterial flagellin, whereas a NAIP2–NLRC4 complex confers specificity for recognition of the *S. typhimurium* rod protein PrgJ. In humans, NLRC4 and the sole human NAIP serve as sensors for the bacterial T3SS needle protein (Kofoed and Vance, 2011; Yang *et al.*, 2013; Zhao *et al.*, 2011). Activation of caspase-1 through a NLRC4 dependent pathway has also been associated with subsequent cell death, termed pyroptosis, which can take place independent of ASC (Miao *et al.*, 2010a; Broz *et al.*, 2010).

NLRP1 was the first inflammasome-forming NLR to be described (Martinon *et al.*, 2002). NLRP1 is expressed in diverse cell types including myeloid cells, T and B cells. In humans, NLRP1 is a single copy gene which encodes a N-terminal PYD, a NBD/NOD, a LRR domain, a function-to-find domain (FIIND), and a C-terminal CARD. Mice encode three polymorphic forms of NLRP1 proteins (*Nlrp1a*, *Nlrp1b*,

and *Nlrp1c*), which lack functional PYD and FIIND domains. Genetic studies have shown that the *NLRP1b* gene is the primary mediator of mouse macrophage susceptibility to *Bacillus anthracis* lethal toxin (LT) in sensitive strains such as BALB/c. Upon exposure to LT, NLRP1 activates caspase-1 resulting in production of mature IL-1 β and pyroptosis. Some proposed mechanisms of LT-induced cell death include cleavage of mitogen-activated protein kinase kinases (MEKs), impairment of mitochondrial function, ATP leakage, lysosomal membrane permeabilization, and cathepsin B release, proteasome-mediated protein degradation, potassium efflux, caspase-1-mediated macrophage necrosis, and inflammasome activation with release of IL-1 β and IL-18; however, the mechanism of activation of the NLRP1 inflammasome by LT remains unclear (Alileche *et al.*, 2006; Averette *et al.*, 2009; Muehlbauer *et al.*, 2007; Wickliffe *et al.*, 2008). In addition, both human and mouse NLRP1 can be activated by muramyl dipeptide (MDP). MDP was suggested to induce conformational changes in NLRP1, which enable its oligomerization, thus creating a platform for caspase-1 activation (Faustin *et al.*, 2007). A NLRP1–NOD2 interaction has also been shown to be required for optimal responses to LT and MDP *in vivo* (Hsu *et al.*, 2008).

Recent studies have uncovered host regulatory mechanisms and pathogen immune-evasion strategies targeting inflammasome function, further emphasizing the importance of inflammasomes in the antimicrobial response. For instance, mouse effector and memory CD4⁺ T cells have been shown to suppress NLRP1 and NLRP3 inflammasome-mediated caspase-1 activation and subsequent IL-1 β release by select TNF family ligands in a cognate manner (Guarda *et al.*, 2009), and type 1 IFNs repress the activity of NLRP1 and NLRP3 inflammasomes through a STAT-1-dependent mechanism (Guarda *et al.*, 2011). Human NLRP1 is regulated by interactions with the anti-apoptotic proteins Bcl-2 and Bcl-X_L, which bind and suppress NLRP1, reducing caspase-1 activation and IL-1 β production (Bruey *et al.*, 2007). NLRP1 is also targeted by viruses to evade innate immunity. For instance, Vaccinia virus F1L protein, a viral homolog of the cellular Bcl-2 protein, has been demonstrated to bind and inhibit NLRP1 through a small hexapeptide in F1L thereby promoting viral virulence (Gerlic *et al.*, 2013). In another example, Kaposi's sarcoma herpes virus (KSHV) Orf63 was found to be a viral homolog of human NLRP1 that interacts with NLRP1 and blocks NLRP1-dependent innate immune responses, thereby contributing to reactivation and generation of progeny virus. KSHV Orf63 was also shown to inhibit the NLRP3 inflammasome (Gregory *et al.*, 2011).

Many newly emerging aspects of the biology of NLR proteins point to functions that transcend pathogen detection and inflammation to include autophagy (e.g., autophagic responses to bacteria are regulated by NOD2, NLRC4), tissue homeostasis (e.g., NLRP3 functions as a key regulator of intestinal homeostasis), transcriptional regulation (e.g., CIITA and NLRC5 function as transcriptional regulators of major histocompatibility complex I and II respectively), as well as nonimmune functions such as embryonic development (NLRP5, NLRP2), and reproduction (NLRP7, NLRP14) (Kuffer and Sansonetti, 2011). NLRs can act as negative or positive regulators of a variety of signaling pathways. For instance, NLRC3 acts as a negative regulator of T cell activation, NLRP2,

NLRP4, NLRP6, NLRP12, and NLRC5 inhibit NF- κ B activation, and NLRC5 and NLRX1 negatively regulate type 1 IFN signaling pathways. On the other hand, activating roles have been reported for NLRP12 and NLRP2 in activation of caspase-1, NLRX1 in ROS production, and NLRC5 in IFN-dependent antiviral responses (Lich and Ting, 2007). Thus NLRs may have diverse roles depending upon the cell type and the infectious context (Table 3).

The critical role of NLRs in physiology is further underscored by their clear implication in several human autoinflammatory and autoimmune diseases. Mutations in NLRP3 and NLRP12 lead to hereditary periodic fever syndromes, while mutations in NOD2 are linked to inflammatory bowel disease, Crohn's disease or Blau syndrome (Zhong *et al.*, 2013). The NLRP3 inflammasome has also been implicated in diseases associated with metabolic dysfunction such as obesity, gout, type 2 diabetes and insulin resistance, atherosclerosis, and Alzheimer's disease due to increased activation of caspase-1 and IL-1 β downstream of NLRP3 triggered by diverse danger signals depending upon the disease context (Vandanmagsar *et al.*, 2011; Masters *et al.*, 2010; Duewell *et al.*, 2010; Heneka *et al.*, 2013). Polymorphisms in NLRP1 are associated with a variety of autoimmune disorders including vitiligo, celiac disease, type 1 diabetes, autoimmune thyroid disorders, systemic lupus erythematosus, rheumatoid arthritis, and

Alzheimer's disease (Zhong *et al.*, 2013). Genome-wide association studies (GWAS) have identified linkage of polymorphisms and/or mutations in NLR genes with a host of other human diseases; these are summarized in Table 3. Given the essential role of NLRs in human disease, future studies investigating the activating ligands, physiological roles and signaling pathways triggered by diverse NLRs will be key to providing fundamental insights into not only how NLRs normally function but also for addressing the molecular basis of aberrant NLR function in patients.

RLRs

The RLRs serve as cytosolic sensors of RNA. RLR family members include retinoic acid-inducible gene 1 (RIG-I), melanoma differentiation factor 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) which differentially regulate viral RNA detection (Table 4). They are characterized by three distinct domains: a C-terminal domain (CTD), a central DExD/H box helicase domain for RNA binding, and two N-terminal CARD domains, that mediate downstream signaling; these N-terminal CARDs are present in RIG-I and MDA5 but not in LGP2 (Figure 1). RIG-I preferentially binds to short (<300 bp) double-stranded (ds) RNAs that have blunt ends and a 5' triphosphate (5'-ppp) moiety while MDA5

Table 4 Summary of select human nucleic acid sensors, their ligands, responses and associated diseases

Sensor class	Nucleic acid sensor	Ligand(s)	Response	Associated diseases
RLR	RIG-I	5'ppp-dsRNA Viruses: Sendai, Influenza, Newcastle disease, Japanese encephalitis, measles, Vesicular stomatitis, Dengue, Hepatitis C, Rabies	Type 1 IFN	Multiple sclerosis, Type 1 diabetes, psoriasis, rheumatoid arthritis
RLR	MDA5	dsRNA, Poly(I:C) Viruses: Picornavirus, Sendai, Encephalomyocarditis, Rotavirus, Dengue, Rabies	Type 1 IFN	Type 1 diabetes
Other	DAI	B-form dsDNA Pathogens: Human cytomegalovirus, HSV-1, <i>Streptococcus pneumoniae</i>	Type 1 IFN through IRF and TBK1 pathways.	
Other	DDX41	B-form dsDNA Viruses: Adenovirus, HSV-1, Vaccinia	Type 1 IFN through STING pathway	
Other	RNA pol III	B-form dsDNA Pathogens: Epstein-Barr virus, Adenovirus, <i>Legionella pneumophila</i>	Type 1 IFN production through RIG-I pathway	
ALR	AIM2	B-form dsDNA Pathogens: Vaccinia virus, HSV-1, <i>Francisella tularensis</i> , <i>Listeria monocytogenes</i>	Inflammasome formation resulting in IL-1 β and IL-18 and cell death by pyroptosis; NF- κ B activation	Systemic lupus erythematosus
ALR	IFI16	dsDNA, sequence-independent, 70 >> 50 bp Viruses: HSV-1	Type 1 IFN through STING pathway, inflammasome formation in nucleus of Kaposi-sarcoma associated herpes virus (KSHV) infected endothelial cells	Systemic lupus erythematosus
ALR	PYHIN1		STING-dependent IFN production	Asthma in African Americans

preferentially recognizes long dsRNA strands (>1000 bp) with no end specificity (Kato *et al.*, 2008; Hornung *et al.*, 2006; Pichlmair *et al.*, 2006). Both may recognize chemically synthesized dsRNA such as poly I:C or RNA analogs. While 5'ppp-dsRNA exhibits maximal binding affinity, RIG-I is also capable of binding single-stranded (ss) RNA molecules, although with lower affinity (Wang *et al.*, 2010). RIG-I and MDA5 have been reported to have both differential and redundant roles in sensing RNA viruses. RIG-I recognizes mainly negative-sense ssRNA viruses or positive-sense ssRNA/dsDNA viruses including those in the paramyxoviridae, orthomyxoviridae, rhabdoviridae, bunyaviridae families, and some flaviviruses such as Japanese encephalitis and hepatitis C virus; in contrast, MDA5 was shown to primarily detect the dsRNA intermediate form generated during replication of positive ssRNA viruses such as those in the picornaviridae family (Kato *et al.*, 2005, 2006; Loo *et al.*, 2008). However, both are required for an optimal response to West Nile virus, dengue virus, reoviruses, and some paramyxoviruses such as Sendai and measles virus. While RIG-I and MDA5 may differentially detect RNA viruses, they are thought to trigger similar downstream signaling cascades (Yoneyama *et al.*, 2005). In both cases, the ligand-bound RLR engages the mitochondrial or peroxisomal adaptor protein MAVS to activate the cytosolic protein kinases IKK and TANK-binding kinase 1 (TBK1), which in turn activate the transcription factors NF- κ B and IRF3, resulting in production of type 1 IFN and other inflammatory antimicrobial cytokines (Figure 2).

Recent structural studies of RIG-I bound to dsRNA have contributed toward a better understanding of ligand binding and activation of RIG-I. In its inactive form, RIG-I is in an auto-repressed, open conformation whereby the RIG-I CARD motifs sequester the helicase domain. Upon binding of the helicase and CTD with dsRNA and ATP, the protein rearranges into a closed conformation that exposes the CARDs which then interact with the N-terminal CARD of the adaptor protein MAVS to induce NF- κ B and IRF3 activation and establish an antiviral state (Kowalinski *et al.*, 2011). The CARDs of RIG-I have been shown to nucleate the aggregation of MAVS into self-propagating prion-like structures that activate IRF3 (Hou *et al.*, 2011). It is hypothesized that such MAVS polymers may serve to quickly amplify signaling. The prion-like nature of MAVS polymerization bears resemblance to ASC aggregation observed during inflammasome assembly discussed previously, and is under tight regulation to achieve the optimal balance between the antiviral response and unchecked tissue damaging inflammation (Reikine *et al.*, 2014). These regulatory mechanisms include posttranslational modifications such as polyubiquitination and phosphorylation/dephosphorylation of RIG-I and MDA5 that are critical for their immune signaling ability (Gack *et al.*, 2010; Zeng *et al.*, 2010; Wies *et al.*, 2013). Furthermore, signaling may be modulated by virally encoded factors that manipulate these posttranslational modifications (PTMs) or cause proteolytic degradation and cleavage of MAVS (Gack, 2014), as well as by numerous host proteins including the third RLR LGP2 that has been reported to have stimulatory and inhibitory effects on MDA5 and RIG-I signaling respectively (Zhu *et al.*, 2014). Further investigations are needed to clarify the role of LGP2 in antiviral immunity.

AIM2-Like Receptors and Other Intracellular DNA Sensors

Cytoplasmic DNA derived from infectious agents like viruses that replicate in the cytosol or from dying host cells can act as a danger signal to alert the immune system to infection or altered cellular homeostasis. A number of proteins that mediate cytoplasmic surveillance of host- or pathogen-derived DNA have been identified in recent years, however their role in host defense and/or autoimmunity and the mechanistic aspects of their activation are just beginning to be elucidated. These include the AIM2-like receptors (ALRs) (Hornung *et al.*, 2009), DAI (Takaoka *et al.*, 2007), and multiple DNA sensors that engage the ER-localized adaptor protein STING (Ishikawa and Barber, 2008; Holm *et al.*, 2013) resulting in the production of type 1 IFN.

STING binds cyclic dinucleotides (CDNs), second messengers synthesized by bacteria or by the receptor cyclic GMP-AMP synthase (cGAS), which synthesizes noncanonical CDNs from dsDNA (Yin *et al.*, 2012; Burdette *et al.*, 2011; Zhang *et al.*, 2014). STING contains an N-terminal transmembrane region and a cytosolic C-terminal domain (CTD) that interact in a dimerized complex in the absence of CDNs. Upon ligand binding, the CTD is released allowing it to interact with TBK1 and IRF3 (Ouyang *et al.*, 2012). Phosphorylated IRF3 in turn binds to the *Irnf* promoter, resulting in IFN- β synthesis (Figure 2). Several DNA sensors have been shown to act through the STING pathway, including several members of the ALR family discussed below.

DAI was the first TLR-independent cytosolic DNA sensor to be reported. It recognizes long strands (~500-1 kb in size) of dsDNA in its canonical B-form. Upon sensing of dsDNA by DAI, a TBK1 and IRF3-dependent signaling cascade is initiated, resulting in the production of type 1 IFN (Takaoka *et al.*, 2007). Whether or not STING is also required has not yet been fully elucidated. Activated DAI has also been shown to recruit the receptor-interacting protein kinases RIP1 and RIP3, leading to NF- κ B activation (Rebsamen *et al.*, 2009). Subsequently, the DDX41 DExD/H box helicase was also shown to bind intracellular B-form DNA or CDNs leading to a type 1 IFN response (Parvatiyar *et al.*, 2012; Zhang *et al.*, 2011). The signal is transduced by direct binding of activated DDX41 to STING which results in phosphorylation of IRF3 through TBK1. Cytosolic DNA may also be detected through the actions of RNA Polymerase III, which transcribes dsDNA to 5'-ppp RNA. The RNA is in turn sensed by RIG-I, resulting in a RIG-I-mediated IFN and NF- κ B response (Ablasser *et al.*, 2009; Chiu *et al.*, 2009). This pathway has been implicated in sensing intracellular bacteria, like *L. pneumophila*, and DNA viruses, like Epstein-Barr virus, Herpes simplex virus (HSV)-1, and adenovirus.

Five AIM2-like receptors (ALRs) have been identified in humans and 13 in mice. These are members of the Pyrin and HIN domain (PYHIN) family encoded by an IFN-inducible gene cluster on chromosome 1. In humans, they comprise of AIM2, IFN- γ inducible protein 16 (IFI16), myeloid cell nuclear differentiation antigen (MNDA), pyrin and HIN domain family member 1 (PYHIN1), and the recently identified pyrin domain only protein 3 (POP3) (Table 4). They are characterized by a N-terminal PYD and/or a C-terminal hematopoietic IFN-inducible nuclear protein (HIN)

domain (Figure 1). The HIN domain contains partially conserved repeats that allow for binding of DNA ligands resulting in activation of the inflammasome, type 1 IFNs or both depending upon the ALR. For instance, detection of DNA by AIM2 leads to assembly of an inflammasome resulting in activation of caspase-1 and production of active IL-1 β (Hornung *et al.*, 2009; Fernandes-Alnemri *et al.*, 2009), PYHIN1 activates STING-dependent IFN production (Brunette *et al.*, 2012), while IFI16 can lead to inflammasome activation or STING-dependent activation of type 1 IFN (Kerur *et al.*, 2011; Unterholzner *et al.*, 2010). AIM2 is perhaps the best studied of the ALRs. Recent structural studies have advanced our understanding of how AIM2 binds DNA to activate immune responses. Electrostatic interaction between positively charged HIN domain residues and the dsDNA sugar-phosphate backbone allows for nonsequence-specific DNA recognition by AIM2 (Jin *et al.*, 2012). In the inactive state, the HIN and PYD domains complex to maintain the molecule in an auto-inhibited conformation. Binding of dsDNA to the HIN domain opens the protein conformation releasing the PYD domain, which is then free to engage the adaptor protein ASC resulting in assembly of the AIM2 inflammasome that culminates in production of active IL-1 β and IL-18. However, the AIM2 inflammasome differs from the NLR inflammasomes in that the protein scaffold centers not on protein oligomerization domains but on multiple AIM2 molecules binding to the same dsDNA ligand. Nevertheless, AIM2 interaction with the adaptor ASC may initiate prion-like self-polymerization of ASC into large, stable filaments which have been shown to be both necessary and sufficient for AIM2 inflammasome responses (Cai *et al.*, 2014; Lu *et al.*, 2014). Given the polymeric nature of inflammasome assembly, it is anticipated that AIM2 activation must be under strict regulation; however, the regulatory mechanisms are poorly understood to date. Recently POP3, a newly identified member of the ALR gene cluster has been shown to negatively regulate DNA virus induced activation of the AIM2 and IFI16 inflammasomes by inhibiting recruitment of ASC to these ALRs (Khare *et al.*, 2014). Additionally, activation of IFI16 is also regulated by viral proteins that degrade IFI16 or block its oligomerization thereby interfering with the antiviral response (Orzalli *et al.*, 2012; Li *et al.*, 2013b).

Emerging data suggest that apart from host defense, DNA sensors may also be involved in development of autoimmune disease resulting from persistent triggering of these sensors by accumulated endogenous DNA (Holm *et al.*, 2013). Inefficient removal of chromatin due to defects in deoxyribonuclease 1 is associated with SLE (Napirei *et al.*, 2006), while mutations in the gene encoding three prime repair exonuclease 1 (TREX1), a negative regulator of STING signaling, result in Aicardi-Goutières syndrome (AGS), a severe neurological brain disease (Crow *et al.*, 2006). Thus, innate immune detection of DNA results in different functional outcomes, i.e., either host defense or pathology, depending upon the biological context. The field of DNA sensing is still burgeoning, and it will be interesting to gain a fuller understanding of the mechanisms underlying the beneficial and pathological consequences of innate recognition of DNA, while exploring the prospect of using nucleic acids as agents to promote antiviral immunity.

Role of Intracellular Organelles and Spatial Relocation

Activation of innate sensors following ligand binding may be manifested not only through changes in protein conformation and phosphorylation, but also through their spatial relocation (Figure 2). Following activation, the cytoplasmic sensors RIG-I, MDA5, and NLRP3 move from the cytoplasm to the mitochondria where they associate with MAVS (Seth *et al.*, 2005; Subramanian *et al.*, 2013). This relocation is essential for signal propagation; dislocation of MAVS from mitochondria abolishes RIG-I-dependent type 1 IFN and NLRP3-dependent inflammasome activation in response to RNA viruses (Seth *et al.*, 2005; Park *et al.*, 2013). AIM2 relocates from the cytosol to ASC foci upon activation by DNA. Likewise, all other murine ALRs translocate from the nucleus to puncta containing the adaptors ASC, STING, or both in discrete patterns under co-expression conditions (Brunette *et al.*, 2012). STING itself relocates within the cell following activation. In its inactive state, STING is present on the endoplasmic reticulum (ER), the mitochondria, and/or the mitochondria-associated ER membranes, which tether the ER to the mitochondrion (Ishikawa and Barber, 2008; Zhong *et al.*, 2008). Upon activation, STING moves to 'concentrated puncta' within the cell. These foci have been proposed to be associated with autophagy; however the association between STING activation and autophagy remains unclear (Burdette and Vance, 2013).

In addition to signal transduction, spatial relocation may also influence the outcome of signaling by determining the nature of the downstream response. Perhaps the best studied example is that of TLR4, which senses extracellular LPS. Activation of TLR4 on the plasma membrane results in its dimerization followed by binding to MyD88 and TIRAP/MAL adaptor proteins. This complex is trafficked to lipid rafts ultimately resulting in activation of NF- κ B and expression of pro-inflammatory cytokines. However, TLR4 may also engage the adaptors TRIF and TRAM resulting in phosphorylation of IRF3 and ultimately in production of type 1 IFN. For this latter pathway to be initiated, complex assembly must occur in early endosomes (Gangloff, 2012). Thus movement of TLR4 from the plasma membrane to the endosomes switches the outcome of signaling from production of NF- κ B-dependent cytokines to type 1 IFN. Likewise, TLR9 in most cells traffics from the ER through the golgi to proteolytically active early endosomal compartments where it is activated by cleavage of its ectodomain, facilitating signaling through NF- κ B to activate pro-inflammatory cytokines. In plasmacytoid DCs however, cleaved TLR9 in endosomes interacts with the adaptor protein (AP)-3 complex which delivers it to specialized lysosome-related organelles, where TLR9 can engage the TRAF3 and IRF7 signaling pathway resulting in induction of type 1 IFN (Honda *et al.*, 2005; Sasai *et al.*, 2010). A third example is that of the cytoplasmic RNA sensor RIG-I that can engage its adaptor MAVS from both peroxisomal and mitochondrial locations. Following viral infection, peroxisomal MAVS induces IRF1-dependent but type 1 IFN-independent rapid expression of IFN-stimulated genes (ISGs) and defense factors that may provide immediate protection, whereas mitochondrial MAVS activates IRF3 and type 1 IFN-dependent expression of ISGs

with delayed kinetics, that may serve to amplify and stabilize the antiviral response (Dixit *et al.*, 2010). More recently, it has been demonstrated that signaling via mitochondrial MAVS induces IFN- β and IFN- λ , while peroxisomal MAVS selectively activates an IFN- λ response (Odendall *et al.*, 2014). In all these instances, the intracellular movement of the innate sensor and/or its signaling adaptor to specific subcellular compartments determines the nature of the response.

The significance of this spatial relocation is not completely understood. It seems possible that the cellular location of ligand detection or pathogen replication is not always the best location for signal propagation. Nuclear ALRs, for instance, may be appropriately positioned to sense dsDNA in the nucleus where viral DNA is undergoing replication, however once activated move to a site where the downstream signaling components are located (Brunette *et al.*, 2012). Organelle membranes could provide ideal platforms for solid-phase oligomerization of innate sensors and/or their adaptors leading to assembly of active complexes, thereby allowing the input signal to be quickly amplified to ensure a robust innate response. Additional, as yet unidentified, molecules on organelle membranes might also be required for a complete functional response. Mitochondria, for instance, have been shown to directly contribute to bactericidal activity through the generation of ROS upon stimulation of a subset of TLRs. This response involves translocation of the TLR signaling adaptor, TRAF6, to mitochondria where it engages evolutionarily conserved signaling intermediate in Toll pathways (ECSIT), a protein that participates in mitochondrial respiratory chain assembly, resulting in increased mitochondrial ROS generation (West *et al.*, 2010). We speculate that relocation of innate immune signaling components to organelles such as mitochondria may contribute to or enhance microbicidal and/or other yet unknown responses. Mitochondria also play a role in regulating the apoptotic response to stress signals (Wang, 2001), and localization of innate signaling complexes on mitochondria could allow for the integration of signals from innate immune and cell death pathways.

Combinatorial Sensing and PRR Crosstalk

Innate sensing of pathogens is a complex, interconnected system of receptors, adaptors, and signaling pathways. A single pathogen may be detected by multiple receptors; for example, *Mycobacterium paratuberculosis* infection is sensed by TLR2, TLR4, and NOD2 (Ferwerda *et al.*, 2007) while rhinovirus infection of bronchial epithelium is sensed by TLR3, RIG-I, and MDA5 (Slater *et al.*, 2010). Activation of each of these receptors initiates distinct as well as common signaling cascades, which must be synthesized by the cell into an effective immune response. Crosstalk between innate immune signaling pathways is therefore an essential determinant of the quality and magnitude of the ensuing host response. Cooperation between multiple signaling pathways may be important for mounting an appropriate response to an elicitor. For example, concomitant activation of the CLR Dectin-1 and TLR2, both of which sense fungal cell wall components, is required to induce optimal cytokine responses in macrophages. This collaboration requires Dectin-1 signaling through

the Syk pathway, and can also occur with TLRs 4, 5, 7, and 9 that like TLR2, signal via the adaptor MyD88. Activation of Dectin-1 alone induces no TNF and activation TLR2 induces a low level of TNF. However activation of both Dectin-1 and TLR2 results in sustained degradation of I κ B, enhanced nuclear translocation of NF- κ B, and a synergistic TNF response (Dennehy *et al.*, 2008). In another study, collaboration between TLR2 and TLR9 was required for optimal host resistance to *Mycobacterium tuberculosis* (Bafica *et al.*, 2005). Signal integration from multiple pathways may thus be important for the cell to mount a scaled, robust, specifically tailored response to a pathogen, while decreasing potential 'noise' from commensal microbes and/or homeostatic cellular functions.

Sequential activation of multiple PRR pathways may enable the cell to generate an optimal response to contain a potential pathogen while minimizing immunopathology. For instance, in conventional DCs, a subset of herpes simplex viruses is first detected by cell surface TLR2 interacting with the virions, and then by intracellular TLR9 that senses viral genomic DNA (Sato *et al.*, 2006). In another study, sequential activation of MyD88-independent and MyD88-dependent cytokine responses by the intracellular bacterium *Listeria monocytogenes* was required for monocyte recruitment to infected tissue and monocyte activation respectively (Serbina *et al.*, 2003). Finally, NLRP3 inflammasome activation requires successive activation of the TLRs and NLRP3 (Netea *et al.*, 2009; Bauernfeind *et al.*, 2009). A TLR-activating stimulus first induces NF- κ B-dependent upregulation of pro-IL-1 β and NLRP3. A second NLRP3-activating stimulus then triggers assembly of the inflammasome resulting in processing of procaspase-1 to its active form, which in turn cleaves the pro form of IL-1 β to generate active cytokine. Both TLR and NLR pathways are therefore essential for induction of a complete IL-1 β response in macrophages.

Innate immune signaling pathways may also negatively regulate each other. For instance, the RLR-stimulated response has been shown to interfere with TLR signaling. The RLR-activated transcription factor IRF3 dominantly binds to the promoter region of the interleukin-12b (*Il12b*) gene, out-competing TLR-induced IRF5. As a consequence, activation of RLRs in mice attenuates TLR-induced T helper type 1 (Th1) and interleukin 17-producing helper T cell (Th17) responses, and pre-infection of mice with a virus reduces their ability to respond to bacterial pathogens effectively (Negishi *et al.*, 2012). Likewise, NLRX1 has been proposed to interact with TRAF6 thereby inhibiting NF- κ B signaling in response to LPS stimulation. Additionally, NLRX1 acts as a negative regulator of RIG-I signaling by interfering with RIG-I–MAVS interaction. Consequently, *Nlrp1* $-/-$ mice exhibit increased expression of antiviral signaling molecules and pro-inflammatory IL-6 after influenza virus infection, and this increased inflammation is associated with marked morbidity and tissue pathology in *Nlrp1* $-/-$ mice (Allen *et al.*, 2011). Negative regulation may also occur by sensors within the same PRR family. For example, within the TLR pathway, the adaptor MyD88 inhibits the TLR3-TRIF dependent response, which may protect the host from immunopathology associated with excessive production of IFN- β (Johnson *et al.*, 2008; Siednienko *et al.*, 2011). Within the NLR family, NLRP7 has been shown to negatively regulate the NLRP3 inflammasome by

direct interaction with procaspase-1 and pro IL-1 β (Radian *et al.*, 2013). Finally, although not as well characterized, several members of the NLR family have been proposed to have anti-inflammatory functions. NLRP6, NLRP10, NLRP12, NLRC3, and NLRX1 have all been reported to negatively regulate canonical or noncanonical NF- κ B activation and subsequent cytokine responses (Allen, 2014).

Crosstalk occurs not only between innate signaling pathways, but also between innate and other cellular pathways. For example, mTOR, which is usually involved in cell growth and metabolism, has also been shown to limit pro-inflammatory responses to bacterial stimuli by blocking NF- κ B activation and conversely increase anti-inflammatory cytokines like IL-10 by enhancing STAT3 activity, thereby limiting the priming of Th1 and Th17 cells (Weichhart *et al.*, 2008). Moreover, in the context of an infection, crosstalk also occurs between the host and pathogen. Many pathogens can modulate the host response, allowing them to overcome or bypass host defense mechanisms. For instance, the human cytomegalovirus actively cleaves host DNA and disrupts the ability of the infected cell to repair it, while selectively maintaining nucleotide excision repair of the viral genome (O'Dowd *et al.*, 2012). Likewise, many viral pathogens actively cleave or sequester components of innate immune pathways to disrupt signaling, while intracellular bacterial pathogens such as *Salmonella enterica* and *Mycobacterium tuberculosis* have developed strategies to avoid, modulate, or hijack the host immune response in their favor (Forrellad *et al.*, 2013; Gack, 2014; de Jong *et al.*, 2012; Figure 3). Interplay between PRR and other cellular pathways as well as between the host and the pathogen, are therefore essential parameters that influence the outcome of infection.

Multiscale Regulation of Cytosolic Sensing Pathways

Successful host defense against pathogens requires development of an appropriate, scaled immune response commensurate with the nature of the threat, a process that involves dynamic, feedback-controlled interactions between immune system components at multiple molecular and cellular levels. Information is integrated from the genomic, transcriptional and translational levels, posttranslational controls, protein–protein interactions, assembly of functional multiprotein complexes and their appropriate cellular localization, to coordinate a successful effector response against the potential pathogen, followed by induction of appropriate negative regulatory mechanisms to restore cellular homeostasis (Figure 3). Information from heterogeneous cells must further be integrated into an organ- and organism-level response. Regulation at each level affects the response at many others; therefore a functional immune response is the result of an orchestrated set of events, with combinatorial regulatory potential. Deciphering the intricate physical and functional interactions that underlie innate immunity will therefore require a global, systems-level understanding of the molecular and cellular networks that comprise the processes at all levels (Subramanian *et al.*, 2015).

This seems a daunting endeavor; however, recent technological advances have allowed for the collection of comprehensive, large-scale ‘omics’ datasets at multiple molecular and cellular levels. Coupled with major developments in

computational modeling and network analysis methodologies, they hold the potential to greatly advance our understanding of innate immune regulation by enabling a systems approach to innate immunity. Genomics, which involves sequencing of entire genomes, has enabled GWAS that permit unbiased association of genetic variants commonly arising due to single nucleotide polymorphisms with disease traits (Xavier and Rioux, 2008). Such studies have revealed association of polymorphisms in cytosolic sensors, particularly the NLRs, with a plethora of autoimmune and autoinflammatory diseases (Zhong *et al.*, 2013; Table 3). A notable example is the association of NOD2 genetic variants with susceptibility to Crohn's disease (Xavier and Rioux, 2008). Transcriptomics, the global analysis of gene expression pathways, has resulted in the identification of novel transcription factors, *cis*-regulatory elements, and previously unknown signaling modules involved in innate immune responses, while ChIP-Seq (chromatin immunoprecipitation followed by sequencing) approaches have allowed for identification of genome-wide binding sites for these transcription factors (Gilchrist *et al.*, 2006; Elkon *et al.*, 2007; Ramsey *et al.*, 2008; Gottschalk *et al.*, 2013). Together with network perturbation strategies such as RNAi, these technologies have allowed for elucidation of gene-regulatory networks controlling the innate immune response (Amit *et al.*, 2011). Transcript profiling has also been used to elucidate immunological responses to vaccine antigens, with the goal of predicting vaccine efficacy and potentially optimizing the immunogenicity of vaccines (Li *et al.*, 2013a). For instance, systems biology approaches have been used to determine the mechanisms involved in conferring immunity to yellow fever (Querec *et al.*, 2009; Gaucher *et al.*, 2008), seasonal influenza (Nakaya *et al.*, 2011) and Human immunodeficiency virus (HIV) (Zak *et al.*, 2012) and to develop computational models that can predict vaccine efficacy in subsequent, independent trials.

Advances in mass spectrometry have further enabled collection of large-scale proteomic datasets for quantification and characterization of proteins and posttranslational modifications (PTMs) in response to various stimuli. For instance, new developments in proteomics technologies have resulted in exciting discoveries of phosphorylation sites and led to an increased understanding of the role of phosphorylation in the immune response (Gottschalk *et al.*, 2013). Formation of functional multiprotein complexes (involving receptor dimerization/oligomerization, interaction with adaptor proteins, and other protein–protein interactions necessary for assembly of the signaling complex) is an essential step that controls signal propagation and critically determines the quality and/or magnitude of the innate response. Protein expression, protein–protein interaction, and PTM data can provide insights into assembly of such functional complexes, and when analyzed using network analysis tools, can also help elucidate complex signaling circuits underlying the innate response (Subramanian *et al.*, 2015). Finally, metabolomics, the comprehensive analysis of metabolites such as metabolic intermediates, hormones, and secondary metabolites, has been used to better understand host–pathogen interactions (Olszewski *et al.*, 2009) and to develop metabolic biomarkers for diseases (Monteiro *et al.*, 2013). Although metabolomics has not been widely employed in the study of innate immunity, it is

Figure 3 Systems-level overview of innate immunity. Development of a functional immune response is dependent on interactions between cellular components and processes at multiple levels. Modifications at the genomic level, such as genetic polymorphisms, affect the sequence of the gene being transcribed, while epigenetic modifications or other effects on DNA regulation influence the amplitude of transcription. An RNA transcript may be regulated by miRNAs, lncRNAs, and other noncoding RNAs, mRNA secondary structure or splicing events that may have profound effects on translation and protein expression. A protein may be further modified posttranslationally by addition of biochemical functional groups (such as phosphates or acetates) or through structural changes (such as formation of disulfide bonds). Sensing of PAMPs and DAMPs by innate sensors initiates the assembly of multiprotein signaling complexes, and the signal may be further propagated through trafficking or spatial relocation of the protein(s) or protein complex to intracellular compartments. Formation of functional signaling complexes is therefore a highly regulated process that results from an integrated set of intracellular events like transcription, translation, posttranslational modifications (PTMs), proper protein trafficking, and localization. The nature and magnitude of the response may also vary depending upon the type of innate immune cell encountered (e.g., macrophage, neutrophil, and B cell) and stochastic variations between single cells of the same type. Pathogens may further modulate or evade the immune response by interfering with host defense mechanisms at multiple levels; some examples are indicated in red. The regulation and integration of these events occurring at various levels determines the eventual effector response that may either result in host protection and restoration of immune homeostasis or unrestrained inflammation leading to tissue damage and/or autoimmunity.

now appreciated that cytosolic sensors, particularly the NLRs play an unequivocal role in sensing danger signals produced during metabolic stress. A role for metabolism in controlling inflammation has also emerged (Kominsky *et al.*, 2010), and future studies should provide greater insight into the metabolic networks controlling innate immunity.

Integrative analysis of high-dimensional data acquired from multiple molecular levels in this manner will be key to

elucidating the complex spatiotemporal interactions that underlie the development of a functional immune response. Advances in network biology have facilitated representation of the intricate interactions at each level as physical or functional networks of interconnected components, which enables recognition of emergent properties arising from these interactions (Subramanian *et al.*, 2015). When substantiated by focused experimentation, this approach holds great promise for accelerating

our understanding of the transcriptional, gene-regulatory, and signaling networks controlling the innate immune response. Integration of the aforementioned global approaches with advances in network biology, computational, and mathematical tools, may thus in future endeavors permit the generation of quantitative and predictive models of innate immunity, which in turn, will empower vaccinology, drug discovery, and other therapeutic possibilities for treatment of human immune disorders.

Introduction

Scavenger receptors (SRs) belong to the vast family of innately encoded pattern recognition receptors – first-line defense molecules as ancient as host–microbe interactions themselves. Given their extreme structural and functional diversity, it may be useful to define what constitutes a true SR. A recent effort to standardize SR nomenclature delineates four major defining features: SRs are cell surface receptors (i.e., transmembrane molecules, as opposed to secreted or intracellular) that share mostly myeloid expression (with an extension to professional scavenging cells like scavenger endothelial cells) (Sørensen *et al.*, 2012); they typically bind multiple ligands that are mostly nonself and modified self, and functional outcomes of ligand recognition include endocytosis, phagocytosis, adhesion, and signaling (PrabhuDas *et al.*, 2014). The present article summarizes structure–function characteristics of SRs throughout evolution, focuses more specifically on innate immune mechanisms and finally links physiological functions of SRs to disease phenotypes and therapeutic advances.

SR-Specific Domains Share Ancient Origins

SRs are grouped in 10 classes based on domain architecture as depicted in Figure 1. Mammalian members are listed in Table 1 alongside related invertebrate members for classes where their existence has been described. Although most domains with SR-defining functions have arisen early during evolution they may not always occur in the same combinations as found in mammalian SRs. A direct consequence of this combinatorial domain organization is the broad binding specificity of SRs, which earned them the nickname ‘molecular flypaper’ (Krieger *et al.*, 1992). Despite the multitude of recognition domains, many receptors share the same ligands, for example, Gram-negative lipopolysaccharide (LPS) or Gram-positive lipoteichoic acid (LTA), and all bind the defining ligand modified LDL. This shared ligand specificity despite structural complexity has been proposed to stem from a similar distribution of electrostatic potential in the three-dimensional structure of many receptors (Canton *et al.*, 2013). Electrostatic interactions are destabilized and permit ligand dissociation in the lower pH environment of endolysosomes, as shown for several SRs (Nielsen *et al.*, 2013; Doi *et al.*, 1994).

The scavenger receptor cysteine rich (SRCR) domain found in class A and class I SRs is part of a larger superfamily based on a ~100 amino acid domain that includes 6 (group A) to 8 (group B) cysteines forming an immunoglobulin-like fold held together by intramolecular disulfide bridges (Hohenester *et al.*, 1999; Sarrias *et al.*, 2004). Group A SRCRs are found in the first identified macrophage SR, SR-AI, and in CD163 (Freeman *et al.*, 1990; Resnick *et al.*, 1994), whereas group B SRCRs are part of lymphocyte surface receptors CD5 and CD6

currently not classified as SRs. The SRCR is required for ligand binding in macrophage receptor with collagenous structure (MARCO) but dispensable for ligand binding in SR-AI, since the shorter isoform, SR-AII, lacks the SRCR but has identical ligand specificity (Brannstrom *et al.*, 2002). SRCRs are often found together with coiled-coils or collagen-like repeats that mediate ligand binding in SR-AI and SR-AII (Rohrer *et al.*, 1990; Kodama *et al.*, 1990), or with C-type lectin-like domains (CTLDs) that bind ligands in COLEC12/SRCL (Nakamura *et al.*, 2001). In *Drosophila*, SRCRs are mostly found in secreted multi-domain immune response proteins that contain enzymatic effector domains such as serine proteases involved in the humoral immune response, suggesting molecular coupling of pathogen detection and immune effector mechanisms (Munier *et al.*, 2004).

The CTLD is a Ca^{2+} -dependent carbohydrate recognition domain found in class A and E receptors. While CTLDs are part of the larger carbohydrate recognition domain family and found in bona fide innate immune receptors for glycans like the mannose receptor or DC-SIGN, the CTLDs in SRs do not necessarily bind glycans, but can also recognize proteins, lipids, or nucleic acids (Zelensky and Gready, 2005). CTLDs are part of surface receptors in lower organisms like nematodes and insects, but combine with functionally different domains compared to vertebrate SRs (Drickamer and Dodd, 1999; Kanost *et al.*, 2004). The LINK domain found in class H SRs shares structural homology with C-type lectins, but does not bind glycosaminoglycans (Prevo *et al.*, 2004).

Another recurrent domain is the 30–40 amino acid EGF-like fold found in class F and class H receptors. Like the SRCR, the EGF-like domain is cross-linked by disulfide bridges and occurs in a variety of cell surface and secreted molecules. Laminin, found in class H SRs, is a subtype of EGF-like domains distinguished by four instead of three disulfide bridges (Wouters *et al.*, 2005). A common feature of EGF-like and EGF-laminin domains is their occurrence in tandem or multicopy repeats and a role in extracellular matrix adhesion (see Section SRs Contribute to Cell Adhesion). In class H SRs, EGF-like domains are interspersed with another extracellular matrix (ECM) adhesion domain, the evolutionarily ancient fasciclin domain (FAS1) found both in plants and animals.

Additional domains specific to single SR classes include immunoglobulin-like domains found in class J SRs, and the lysosome-associated membrane glycoprotein (LAMP) and mucin domains found in CD68, the single class D SR. LAMPs are primarily found in lysosomal and endosomal proteins, reflected by the preferred endosomal localization of CD68.

Finally, the CD36 fold exclusive to class B SRs is found both in plasma membrane receptors and lysosomal membrane proteins (Calvo *et al.*, 1995). Its characteristic ‘hairpin’ topology with two transmembrane passes forms a hydrophobic tunnel that channels neutral lipids across

Figure 1 Human scavenger receptor classes and functional domains. Adapted from Canton, J., Neculai, D., Grinstein, S., 2013. Scavenger receptors in homeostasis and immunity. *Nature Reviews Immunology* 13, 621–634; PrabhuDas, M., Bowdish, D., Drickamer, K., *et al.*, 2014. Standardizing scavenger receptor nomenclature. *Journal of Immunology* 192, 1997–2006, based on SMART and InterPro domain representations for human members of scavenger receptor families. Cytosolic tails are represented by red bars, transmembrane domains by blue boxes. Domain repeats are indicated by subscript numbers; no number means the domain is present as single copy. CCP, complement control protein; EGF, epithelial growth factor; FAS1, fasciclin 1; Ig, immunoglobulin; LAMP, lysosome-associated membrane glycoprotein; MAM, meprin, A-5 protein, and receptor protein-tyrosine phosphatase mu; SMB, somatomedin-B; SRCR, scavenger receptor cysteine rich. See also [Table 1](#) for members of each class.

biomembranes (see Sections Class B SRs Mediate Physiological Lipid Transport and SRs as Therapeutic Targets), while its heavily glycosylated extracellular (CD36, SR-BI) or luminal (SCARB2/LIMP2) domain interacts with a variety of ligands ([Neculai *et al.*, 2013](#)).

Class C SRs have so far only been described in insects, and contain a number of domains with dimerization or adhesive properties, including the vitronectin-derived somatomedin-B (SMB) domain, a meprin, A-5 protein, and receptor protein-tyrosine phosphatase mu (MAM) domain, and Sushi/complement control protein domains (CCP). Whether invertebrate class C SRs can functionally substitute class A SRs which are conspicuously absent from invertebrate species ([Whelan *et al.*, 2012](#)), remains to be investigated.

Cell Biology of SRs: Endocytosis and Signaling

Contrary to their extremely varied ectodomains, the cytosolic tail structure of SRs, with the exception of class F, is relatively

simple. Internalization signals have been described in the cytosolic tails of most receptors ([Murphy *et al.*, 2005](#)), and modified LDL uptake was shown early on to proceed through clathrin-coated pits ([Fukuda *et al.*, 1986](#); [Figure 2](#)). Indeed, the dileucine motifs required for interaction with clathrin adaptors have subsequently been identified in a number of SRs. SR-AI is internalized via clathrin-coated pits ([Chen *et al.*, 2006](#)), and internalization rate is modulated by phosphorylation of serine residues in the cytosolic tail ([Fong and Le, 1999](#)). STAB1 is mostly intracellular, with a subpopulation cycling between the plasma membrane and early endosomes ([Prevo *et al.*, 2004](#)), and both STAB1 and STAB2 associate with the clathrin adaptor AP2 for early endosome localization ([Hansen *et al.*, 2005](#)). Further, two binding sites for the Golgi-localized, γ -adaptin ear-containing, adenosine diphosphate ribosylation factor (ARF)-binding (GGA) adaptor mediate shuttling between Golgi and lysosomes but not endocytosis of STAB1 ([Zhang *et al.*, 2009](#)). CD68 resides almost exclusively in endolysosomal compartments and undergoes rapid endocytosis based on a tyrosine motif in its cytosolic tail ([Kurushima *et al.*, 2000](#)).

Table 1 Mammalian scavenger receptor nomenclature with ancestral class members

Class	Proposed name	Current NCBI gene name	Alternative names	Ancestral proteins in this class
A	SR-A1 ^a	MSR1	SR-AI, CD204, SCARA1	Speract receptor in <i>Strongylocentrotus</i>
	SR-A3	SCARA3	MSRL1, APC7 ^b	
	SR-A4	COLEC12	SCARA4, SRCL, CL-P1	
	SR-A5	SCARA5	TESR, NET33	
	SR-A6	MARCO	SCARA2, Ly112 ^b	
B	SR-B1 ^a	SCARB1	SR-BI, CD36L1	Lipid transporters ninaD and Santa-maria in <i>Drosophila</i> Odorant receptor SNMP in <i>Drosophila</i> Phospholipid-binding protein Lmp in <i>Dictyostelium</i> dSR-CI to dSR-CIV, phagocytic receptors in <i>Drosophila</i>
	SR-B2	CD36	SCARB3, FAT, GPIV, PAS4	
	SR-B3	SCARB2	LIMP2, CD36L2, LGP85	
C	SR-C ^c			
D	SR-D1	CD68	gp110, SCARD1, LAMP4, macrophage ^b	
E	SR-E1 ^a	OLR1	LOX-1, SCARE1, CLEC8A	Eater, Nimrod, Draper phagocytic/adhesion receptors in <i>Drosophila</i>
F	SR-F1	SCARF1	SREC-I	
	SR-F2	SCARF2	SREC-II	
G	SR-F3	MEGF10	EMARDD	
	SR-G1	CXCL16	SR-PSOX	
H	SR-H1	STAB1	FEEL-1	
	SR-H2	STAB2	FEEL-2	
I	SR-I1	CD163	M130	
	SR-I2	CD163L1	M160, CD163B	
J	SR-J1 ^a	RAGE	AGER	

^aIndicates a splice variant exists which will be labeled SR-X1.1.

^bIndicates name exclusive to murine protein.

^cMembers of this class have only been described in *Drosophila*. Throughout this article, the NCBI names will be used as the nomenclature discussion is ongoing.

The class B SR SCARB2/LIMP2 lacks tyrosine motifs but is nonetheless targeted directly from Golgi to lysosomes, based on a [DE]XXXL[L] dileucine motif that interacts with the late endosome adaptor AP3 (Vega *et al.*, 1991; Janvier *et al.*, 2003).

LOX-1 undergoes clathrin-independent, dynamin-dependent endocytosis through caveolae, which is dependent on an endocytic motif and palmitoylation of its cytosolic tail (Kumano-Kuramochi *et al.*, 2013; Vohra *et al.*, 2009; Murphy *et al.*, 2008). Similarly, both SCARB1/SR-BI and CD36 are sorted into lipid rafts by a palmitoyl anchor and associate with caveolin (Babitt *et al.*, 1997), but the role of caveolin in cholesterol exchange is debated. SR-BI surface localization and function are posttranslationally controlled in a tissue-specific manner by the PZDK1 scaffold protein interacting with its cytosolic tail (Fenske *et al.*, 2009). Only the cytosolic tail splice variant SR-BII contains a dileucine motif and undergoes clathrin-mediated endocytosis (Eckhardt *et al.*, 2006). A recent effort in phosphoproteomics has identified a heteromeric protein complex associated with CD36 internalization: β 1/2 integrins and the tetraspanins CD9 and CD81 all associate with CD36 in receptor–ligand complexes and promote recruitment of FcR γ , whose ITAM motif is the actual signaling component that engages Src kinases for endocytosis (Heit *et al.*, 2013).

An interesting concept is that of ‘frustrated phagocytosis,’ which postulates that macrophage adhesion mediated by SR interactions with immobilized ligands, such as amyloid- β in plaques, for example, are in fact attempts to endocytose these normally soluble ligands. This concept was tested in SR-A,

which proved that the cytosolic tail motifs required for endocytosis are uncoupled from those required for adhesion (Kosswig *et al.*, 2003). Adhesion requires a short membrane-proximal motif and recruitment of SR-A to cholesterol rich membrane domains (Vadali and Post, 2014). Moreover, initial engagement of SR-A to substrate activates PI3K signaling which promotes a surface increase of SR-A and enhances macrophage adhesion (Cholewa *et al.*, 2010).

Adhesion via SRs induces cell spreading due to cytoskeletal rearrangements, as observed for MARCO and SR-A. SR-A adhesion requires sequential activation of the Src kinase Lyn and PI3K, which leads to paxillin phosphorylation (Nikolic *et al.*, 2007). Likewise, CD36 signals to the actin cytoskeleton and to focal adhesion components by interaction with paxillin (Stuart *et al.*, 2007). SCARF1/SREC-I induces neurite-like protrusions when overexpressed in fibroblasts, through interaction with the actin-binding protein advillin (Shibata *et al.*, 2004).

Signaling downstream of SRs is cell-type specific as exemplified by CD36 engaging different signaling adaptors in endothelial cells, macrophages, and platelets (Silverstein and Febbraio, 2009). Signaling is also context-dependent, and is fine-tuned by differential pairing of SRs with co-receptors when facing bacteria or modified self (see Section SRs Collaborate with Other PRR Families to Fine-Tune Responses). RAGE, LOX-1, and SR-PSOX are reported to trigger pro-inflammatory NF- κ B signaling, with the latter two also activating PI3K/Akt pathways. SR-A and CD36 activate the stress-related p38, JNK, and MAPK modules in response to certain ligands. Interestingly, location defines signal output for

Figure 2 Cell biology of scavenger receptors. Scavenger receptors occupy a range of cellular compartments. Receptors localizing to the plasma membrane can signal upon ligand binding and pair with non-SR receptors to extend their signaling spectrum. Ligand-binding triggers endocytosis via clathrin-coated pits or caveolae. Some receptors are found in lipid rafts. Endocytosed receptors access the endosomal compartment where they can pair with endosomal Toll-like receptors (TLRs) and signal. Maturation of endosomes and fusion with lysosomes leads to acidification and pH-dependent release of ligands from receptors. Ligand degradation products can be exported from endosomes into the cytosol and activate cytosolic sensors like NOD. SRs involved in adhesion to substratum organize focal adhesion points or filopodia by interacting with the actin cytoskeleton. See also main text for details.

SR-A: clathrin-mediated endocytosis triggers ERK signaling, while caveolae-mediated endocytosis triggers p38 and JNK signaling (Zhu *et al.*, 2011). Induction of apoptosis upon ligand-binding has only been reported for SR-A and LOX-1 so far, and may depend on co-stimulation of additional pathways (Seimon *et al.*, 2006).

Transcriptional Control of SR Expression

A defining feature of SRs is their expression on myeloid cells, particularly on resident tissue macrophages, but many are expressed on additional cells, reflecting specialized functions (Figure 3). Class A SRs, for example, are enriched on alveolar

macrophages in the lung, where they contribute to innate immunity against airway pathogens (MARCO and *Streptococcus pneumoniae*, see Section SRs Collaborate with Other PRR Families to Fine-Tune Responses) or against environmental particles (SR-A and silica or asbestos). The class J SR RAGE is uniquely enriched on lung epithelial cells and is involved in lung cancer and fibrosis, but the underlying mechanisms are still largely unclear (Buckley and Ehrhardt, 2010). Class B SRs which mediate lipid transport are highly expressed in tissues of fat metabolism (CD36 in adipose tissue, SR-BI in hepatocytes, and liver Kupffer cells) or steroidogenesis (SR-BI in adrenal glands and testis) (Rigotti *et al.*, 2003; Silverstein and Febbraio, 2009). Many SRs are also particularly enriched in tissues with an immune or first-line defense function, like the

Figure 3 Baseline expression of scavenger receptors in 27 human tissues. The Expression Atlas at the European Bioinformatics Institute (EBI) was used to retrieve gene expression patterns across tissues for all SRs. Shown is a heat-map based on FPKM (fragments per kilobase of exon per million fragments mapped) values obtained by RNA sequencing of coding RNA from tissue samples of 95 human individuals representing 27 different tissues (Fagerberg *et al.*, 2014).

spleen, lung, or appendix. With few exceptions, SRs are up-regulated during monocyte to macrophage differentiation (compare bone marrow to lymph node or spleen expression).

Myeloid expression of SRs is dependent on colony-stimulating factor 1 (CSF-1, also M-CSF) which drives differentiation in the mononuclear phagocyte system (Cecchini *et al.*, 1994). Studies in CSF-1 deficient *op/op* mice (*op* stands for osteopetrotic, given that CSF-1 deficient mice lack osteoclasts and suffer from bone morphogenic defects) identified CSF-1-dependent and -independent macrophage populations, with peritoneal, splenic marginal zone and lymph node sinus macrophage populations fully dependent on CSF-1, and tissue macrophages like liver Kupffer cells, lung alveolar, and intestinal lamina propria macrophages or brain microglia largely independent of CSF-1 (Witmer-Pack *et al.*, 1993). Beyond transcription, CSF-1 can enhance function of certain SRs: CSF-1 not only increases SR-A expression at transcript level, but also stabilizes the receptor and drives its relocation from internal membranes to the cell surface, thereby promoting endocytic and adhesive functions of SR-A expressing macrophages (de Villiers *et al.*, 1994). Major transcriptional regulators of SRs in macrophages are the lipid-responsive nuclear receptors, peroxisome proliferator-activated receptors (PPARs) (Chinetti *et al.*, 2000; Ricote *et al.*, 1998; Tontonoz *et al.*, 1998). SRs and PPARs therefore constitute a double lipid sensing mechanism at the cell surface and in the nucleus that acts in concert to define macrophage differentiation. In addition, immune stimuli such as cytokines modulate SR

expression and define states of macrophage immune activation (Murphy *et al.*, 2005). SR-A in particular is a marker of alternative, T_H2 activated macrophages, which exhibit enhanced endocytic and phagocytic capacities and an anti-inflammatory profile (Gordon and Martinez, 2010).

Evolutionary Origins of SRs and Functions in Host Physiology

Historically, SRs originate from the quest for an endocytic receptor of modified LDL in mammalian macrophages (Goldstein *et al.*, 1979). Evolutionarily, however, SRs carry out a variety of other physiological functions, often related to detection, transport, or clearance of endogenous molecules. SRs are conserved across phyla and found in slime molds, nematodes, fruit flies, sea urchins, and in the primitive chordate amphioxus (Huang *et al.*, 2008; Janssen *et al.*, 2001; Messier-Solek *et al.*, 2010; Rast *et al.*, 2006). Below we list some examples of functional conservation across phyla that highlight roles in host physiology.

Class B SRs Mediate Physiological Lipid Transport

The lipid-binding capacity of class B SRs represents a fascinating example of functional conservation across evolution. In the slime mold *Dictyostelium discoideum*, lysosomal membrane

proteins of the CD36/LIMP2 family bind phosphatidylinositol diphosphates, a type of membrane phospholipid that gives functional identity to endomembranes. By bridging lysosomal compartments and cytoskeletal proteins, the Lmp proteins are thought to facilitate vesicular transport (Karakesisoglou *et al.*, 1999; Janssen *et al.*, 2001). The fruit fly *Drosophila* harbors a relatively high number of CD36-like genes compared to humans (14 in flies vs. 3 in men), which predicts physiologically important functions. Indeed, flies are cholesterol auxotrophs, meaning they rely on cholesterol from their diet. Tissue-specific expression of CD36 genes in *Drosophila* suggests roles in intestinal lipid transport, steroid hormone synthesis, lipid storage, and satiety sensing (Herboso *et al.*, 2011). In particular, the fly CD36 homologs *ninaD* and *Santamaria* were identified as specific docking sites for the uptake and transport of β -carotene from the diet (Kiefer *et al.*, 2002; Wang *et al.*, 2007a). Carotenoids, like cholesterol, are water-insoluble isoprenoid lipids transported on lipoproteins, and are essential for eye development. Fly CD36-like receptors function analogously to mammalian SR-BI, which acts as a docking site for lipoproteins and facilitates cholesterol transport in and out of cells (Rigotti *et al.*, 1997). Moreover, the fly CD36 members *croquemort*, *peste* and *SNMP* are upregulated in steroidogenic tissues during development, where they support ecdysone biogenesis (Talamillo *et al.*, 2013; Herboso *et al.*, 2011), much like SR-BI expression is regulated by hormones in mammalian adrenal glands, where it supports steroid hormone metabolism (Rigotti *et al.*, 2003). SNMPs, other fly CD36 relatives, are expressed in olfactory neurons and detect fatty acid derived pheromones that define social preferences in flies (Benton *et al.*, 2007). A similar sensory function is attributed to intestinal CD36 which detects dietary fatty acids in mammals, translating a preference for fatty foods and the feeling of satiety (Martin *et al.*, 2011).

SRs Contribute to Cell Adhesion

A highly conserved and wide-spread role among SR classes is cell–cell and cell–extracellular matrix adhesion. Many domains described above confer adhesive properties in primitive multicellular organisms: SRCR domains allow reaggregation of conspecific cells in sponges (Blumbach *et al.*, 1998), and a CD36 family member mediates sponge cell interactions with extracellular matrix. The sponge CD36 interaction is particularly intriguing as it is blocked by a protein domain found in thrombospondin, a ligand for mammalian CD36 (Muller *et al.*, 2004). CD36 also mediates fusion between macrophages during giant cell formation, an immune process accompanying granulomatous infections. Here, CD36 is required on one fusion partner for recognition of exposed phosphatidylserine (PS) on the other (Helming *et al.*, 2009). Mammalian SR-A mediates macrophage adhesion to a variety of substrata, including extracellular matrix proteoglycans, apolipoproteins occurring in atherosclerotic lesions, and amyloid deposits in Alzheimer's disease affected brains (Santiago-Garcia *et al.*, 2003; Neyen *et al.*, 2013a; Alarcon *et al.*, 2005).

Our focus below is on EGF-like repeat containing SRs, which present the best documented examples of cross-

evolutionary functional conservation in cell–cell and cell–matrix adhesion.

Class F and H SRs comprise multi-EGF-like repeat receptors, interspersed with EGF-like laminin and fasciclin (FAS1) domains. FAS1 domains appear before the plant–animal split and their adhesive role is exemplified beautifully in the flagellate green alga *Volvox*, which forms spherical colonies of adherent cells. Here, FAS1 domains are part of the algal cell adhesion molecule that tethers together embryonic algal cells (Huber and Sumper, 1994). FAS1 domains are exclusive to mammalian class H SRs (STAB1/FEEL1 and 2), which also play roles in cell–cell interaction and more specifically in vascular epithelial cell adhesion during angiogenesis (Adachi and Tsujimoto, 2002). Invertebrates seem to lack homologs of class H SRs but homologs of class F SRs are well-described in *Drosophila*. They encompass Nimrods and Eater, mainly known for their phagocytic capacity in bacterial clearance (see Section SRs in Innate Immunity), and Draper, involved in apoptotic cell clearance (see Section SRs in Corpse Clearance; Stuart and Ezekowitz, 2008). By domain homology, Nimrods and Draper closely resemble class F SRs based on relatively few extracellular EGF-like domains (1–15) and a longer cytosolic tail that may favor signaling interactions. Eater in particular, with its multiple EGF repeats and short cytoplasmic tail strongly resembles MEGF family members and less class F SRs (Somogyi *et al.*, 2008). Tellingly, *Eater* mutants show a complete deficiency of hemocyte homing to hematopoietic stem cell niches, highlighting a specific role in cell–cell or cell–matrix interaction (Bretscher *et al.*, 2015). Comparable roles in organizing immune tissues are ascribed to non-EGF mammalian SR-AI and MARCO, whose presence is required to maintain the microarchitecture of the spleen and lymph nodes (Chen *et al.*, 2005; Hughes *et al.*, 1995).

Interestingly, detecting self (in the form of a SR family member) can trigger aggregation or repulsion: heterotypic interactions between class F SRs SREC-I and SREC-II contribute to aggregation of fibroblasts (Ishii *et al.*, 2002), while homotypic interactions between the ectodomains of class F receptor MEGF10 or non-SR MEGF11/Jedi ensure correct spacing and subtype distribution of neurons during neuronal patterning in the eye (Kay *et al.*, 2012).

Multiple SRs Mediate Clearance of Normal Self

All SRs are defined by their ability to recognize and endocytose modified lipoproteins, a feature exacerbated by high-fat, high-sugar diets that bring about the inflammatory and oxidative conditions generating these ligands (see Section SRs in Inflammatory Diseases: Innate Immunity to Modified Self). However, in a healthy, normally fed organism, SRs contribute to clearance of a range of physiological ligands.

Class A SCARA5 contributes to iron metabolism by mediating transferrin-independent ferritin uptake (Li *et al.*, 2009). The structurally unrelated class I receptor CD163 also participates in iron metabolism by removing hemoglobin/haptoglobin complexes, thereby facilitating the breakdown of heme and recycling of iron (Kristiansen *et al.*, 2001). In addition to recycling iron, clearance of hemoglobin prevents oxidative damage in the vasculature. Another damage-preventing

clearance mechanism is provided by SR-AI, which binds to and endocytoses calciprotein particles, assemblies of fetuin-A protein and calcium-containing mineral debris that threaten to calcify the vasculature (Herrmann *et al.*, 2012). Class H SRs STAB1 and 2 bear homology to hyaluronan receptors and function as clearance receptors for circulating glycosaminoglycans in vertebrates (Harris and Weigel, 2008).

Finally, several SRs primarily reside and function within endolysosomes. An example is the class B SR SCARB2/LIMP2, which functions as a lysosomal receptor for the lysosomal enzyme β -glucocerebrosidase (Reczek *et al.*, 2007). Deficiency of lysosomal enzymes causes lysosomal storage disorders, for example, Gaucher's type diseases where the efficient cellular breakdown of waste products within lysosomes is impaired (see Section Rare Monogenic Diseases Attributed to SRs).

SRs in Corpse Clearance

SRs, including members from classes A, B, D, E, and F, feature prominently in the removal of apoptotic self during development or tissue injury (Fadok *et al.*, 2001). Alongside other recognition signals, apoptotic cells flip PS from inner to outer membrane leaflet, a process dependent on ABC transporters and other phospholipid scramblases (Ravichandran and Lorenz, 2007). PS and other anionic phospholipids are the most frequently recognized apoptotic cell ligands for SRs, but SRs can mediate both PS-dependent and PS-independent apoptotic cell clearance. Interestingly, PS exposure on viable cells does not constitute an 'eat-me' signal for macrophages, supporting the notion that additional apoptotic signatures are required in PS-dependent cell clearance (Segawa *et al.*, 2011). Apoptotic cell recognition processes are conserved throughout evolution, reflected by usage of the class B SR croquemort (crq) in *Drosophila* (Franc *et al.*, 1999) and SR-BI and CD36 in mammals (Rigotti *et al.*, 1995). An additional, vertebrate-specific corpse clearance system is based on the TAM family of receptor-tyrosine kinases (RTK) (Tyro3, Axl, and Mer) that act alongside SRs and integrins in removing apoptotic cells. TAMs also recognize PS via bridging molecules Gas6 and ProS, which activates RTK signaling. Efficient clearance of apoptotic cells is thought to rely on coupling of RTK signaling via TAMs and phagocytosis via non-signaling SRs, as exemplified by the Mer/SR-A couple (Lemke and Burstyn-Cohen, 2010).

Invertebrate homologs of class F SRs, CED-1 in *Caenorhabditis elegans* and Draper in *Drosophila melanogaster*, are phagocytic receptors that clear apoptotic neurons and guide axons during development (Zhou *et al.*, 2001; Manaka *et al.*, 2004). This role is conserved in mammalian class F receptor MEGF10 and non-SR MEGF12/PEAR1 in phagocytic glial cells (Wu *et al.*, 2009). Microglia also use the non-SR complement receptor CR3 to prune inactive synaptic connections during postnatal neuronal development (Schafer *et al.*, 2012).

Oxidative modifications on circulating lipoproteins bear resemblance to apoptotic cell epitopes, which is why SRs involved in apoptotic cell clearance are usually also contributing to oxLDL uptake in macrophages, causing atherosclerosis (see Section SRs in Inflammatory Diseases: Innate Immunity to Modified Self).

SRs in Innate Immunity

Beyond the defined physiological roles delineated above, all SRs are bona fide pattern recognition receptors (PRRs) and contribute to host defense by recognizing pathogen-associated molecular patterns (PAMPs) (Krieger, 1997). SR-mediated non-opsonic phagocytosis has been shown for hemocyte SRs in invertebrates, and includes phagocytic removal of Gram-positive and Gram-negative bacteria by *Drosophila* class C and H SRs (Kocks *et al.*, 2005; Pearson *et al.*, 1995; Stuart and Ezekowitz, 2008; R  met *et al.*, 2001). Microbial ligands for SRs have been extensively reviewed before (Areschoug and Gordon, 2008, 2009; Mukhopadhyay *et al.*, 2009; Pl  ddemann *et al.*, 2006), and databases exist to match receptors with their microbial ligands (Lata and Raghava, 2008). We chose to highlight some interesting functional aspects of SR-microbe interaction that pin-point contributions of SRs in infectious disease.

SRs Collaborate with Other PRR Families to Fine-Tune Responses

As described above, SRs have generally short cytosolic tails and lack a comprehensive signaling adaptor arsenal. Instead, SRs frequently associate with surface and intracellular PRRs to detect microbes and activate signaling (Underhill and Ozinsky, 2002; Figure 2). Most receptor interactions involve Toll-like receptors (TLRs) and occasionally NOD-like receptors (NLRs), with SRs providing the phagocytic and TLRs/NLRs the sensing/signaling part (Mukhopadhyay *et al.*, 2004).

MARCO contributes to the detection and pro-inflammatory response against mycobacterial trehalose dimycolate by tethering this glycolipid to receptor complexes composed of MARCO, TLR2, and CD14 (Bowdish *et al.*, 2009). In addition, MARCO is required for efficient immune responses against *S. pneumonia* infection in the nasopharynx: by mediating phagocytosis of *S. pneumonia*, MARCO delivers ligands for TLR2 and NOD2 that activate cytokine signaling (Dorrington *et al.*, 2013). Similarly, CD36 collaborates with TLRs in ligand-specific signaling assemblies. Macrophages lacking CD36 are unable to activate antibacterial TLR2/6 signaling in response to diacylated lipopeptides and LTA, revealing a crucial helper function of CD36 in TLR signaling to and clearance of Gram-positive bacteria (Hoebe *et al.*, 2005; Stuart *et al.*, 2005). The Gram-negative bacterium *Neisseria meningitidis* marks an exception: here SR-A-mediated phagocytosis is independent of LPS and uncoupled from TLR4/LPS induced cytokine production (Peiser *et al.*, 2002). Clearance of *Neisseria* in a mouse model of meningococcal septicemia highlights the exclusive role of SR-A in clearing the pathogen and protecting the host from endotoxic shock (Pl  ddemann *et al.*, 2009). Mechanistically, this is thought to be linked to trafficking of TLR ligands by SRs and differential activation of TLR signaling from different cellular compartments. A comprehensive combinatorial study uses mouse mutants of class A SRs SR-AI and MARCO, surface TLR4 and endosomal TLR3, and cytosolic NOD2 and NLRP3 to dissect individual contributions of each receptor. The authors show that class A SRs prevent surface activation of TLR4 signaling by rapid endocytosis of the shared

ligand LPS, but enhance activation of intracellular receptors by increasing ligand availability within the cell (Mukhopadhyay *et al.*, 2011).

Abundant evidence exists on modulation of LPS responses by SRs, which are globally protective against endotoxic shock. A shared mechanism is likely the highly efficient binding and clearance of LPS from the bloodstream (Hampton *et al.*, 1991), although this is mainly due to hepatic SR expression. SR-AI was initially shown to protect against sepsis due to its up-regulation on activated macrophages and efficient clearance of LPS and correlated reduced tumor necrosis factor- α (TNF- α) production (Haworth *et al.*, 1997). A second mode of action is modulation of downstream pro-inflammatory signaling pathways. Quantitative trait linkage (QTL) analysis in laboratory mouse strains has identified the SR-AI locus as relevant for protective, anti-inflammatory IL-10 production after LPS injection (Fulton *et al.*, 2006). Moreover, in endoplasmic reticulum (ER)-stressed macrophages combined activation of SR-AI and TLR4 by LPS leads to pro-apoptotic rather than pro-survival signaling, eliminating a source of pro-inflammatory cytokines (Seimon *et al.*, 2006). Likewise, macrophage expression of SR-BI modulates systemic NF- κ B and stress pathway signaling in response to Gram-negative LPS *in vivo*, a function that also extends to Gram-positive LTA in cultured cells (Cai *et al.*, 2012).

SRs as Microbial Entry Points

Pathogens have coevolved with host surface receptors and abuse their select specificity to gain access to cells. Prominent examples are viruses that attach to surface receptors and use the endocytic machinery to enter and replicate within defined cell types. Class B family members in particular are targeted by virus particles: Hepatitis C virus (HCV) uses SR-BI in concert with CD81 as an entry point into hepatocytes, through specific binding of the viral envelope glycoprotein E2 to SR-BI (Scarselli *et al.*, 2002). Another class B family member, SCARB2/LIMP2, is an entry point for enterovirus and coxsackievirus that cause hand, foot, and mouth disease (Yamayoshi *et al.*, 2009). Beyond virus entry, class B SRs contribute to HCV infection by promoting assembly of lipoproteins that are hijacked by viral particles for dissemination (Burlone and Budkowska, 2009). In a process termed 'apoptotic mimicry' first described for Vaccinia virus (Mercer and Helenius, 2008), a variety of viral families including filovirus, flavivirus, New World arena virus, and alphavirus families exploit the hard-wired mechanisms of PS-dependent apoptotic cell clearance. PS displayed on viral membranes is recognized by PS receptors including TIMs (T-cell Immunoglobulin and Mucin-domain containing proteins) and potentially other PS receptors such as SRs expressed on macrophages, providing a broad nonspecific viral entry mechanism (Jemielity *et al.*, 2013).

SRs also promote entry of bacteria and parasites. In flies, the CD36 family member peste mediates uptake of *Mycobacterium fortuitum*; and in mice, CD36 is required for intracellular survival of *Mycobacterium tuberculosis* (Hawkes *et al.*, 2010; Philips *et al.*, 2005), suggesting ancient coadaptation between mycobacteria and their hosts. The malaria parasite *Plasmodium falciparum* interacts with class B SRs at multiple

stages. SR-BI, along with the tetraspannin CD81, is used by the motile sporozoites to gain entry into hepatocytes and also to provide lipids that support the transformation from sporozoites to the infectious exoerythrocytic form (Rodrigues *et al.*, 2008; Yalaoui *et al.*, 2008). CD36 contributes to the adhesion of Plasmodium-infected red blood cells to vascular epithelium, which allows the parasite to proliferate in the bloodstream and avoid phagocytosis by macrophages. However, the roles of CD36 in *Plasmodium* infection are pleiotropic and include noninflammatory phagocytosis of infected erythrocytes by macrophages, a host-protective feature that has proven a worthwhile therapeutic target (Cabrera *et al.*, 2014; see Section SRs in Metabolic Disease Association Studies and SRs as Therapeutic Targets).

SRs in Inflammatory Diseases: Innate Immunity to Modified Self

It may be puzzling that the host innate immune system should turn on itself. On closer inspection though, the 'self' ligands recognized by SRs are remarkably similar to PAMPs and DAMPs (pattern and danger associated molecular patterns, respectively). Indeed, oxidized lipid epitopes, apoptotic cell epitopes, and certain bacterial lipids are structurally equivalent, and form the basis for the defining feature of SRs – recognition of modified lipoproteins (Binder *et al.*, 2002). Inflammation and oxidation are tightly linked through the release of reactive oxygen species triggered by pro-inflammatory signaling. As a result, chronic inflammation-dependent generation of SR ligands drives disease progression in conditions such as atherosclerosis or Alzheimer's.

All SRs are defined as endocytic receptors for oxidized LDL, and knock-out studies in mice have collectively shown their contributions to cardiovascular disease. Because SRs are not feedback-controlled by intracellular lipid levels as is the case for the LDL receptor, SR-mediated lipid clearance leads to lipid overload in macrophages. Free cholesterol accumulates in the ER and causes macrophage apoptosis, in a process involving ER stress sensing, p38 and JNK signaling, and engagement of SR-AI (DeVries-Seimon *et al.*, 2005). Additional SR-dependent pro-atherogenic mechanisms include pro-inflammatory signaling, angiogenesis, macrophage adhesion to atherosclerotic plaques, and modulation of insulin metabolism, best exemplified in the multitasking SR CD36 (Silverstein and Febbraio, 2009).

Early knock-out studies in mice implicated SR-AI, CD36, and LOX-1 in the development of atherosclerosis, mainly because of their contribution to cholesterol loading (Febbraio *et al.*, 2000; Mehta *et al.*, 2007; Suzuki *et al.*, 1997). However, SR functions in inflammatory/metabolic diseases are more complex than simple cholesterol loading, precluding a clear-cut verdict (Moore and Freeman, 2006).

In addition to lipid overload, high-fat diets also drive insulin resistance and concomitant rises in circulating blood sugar, which causes nonenzymatic glycation of proteins in circulation. Tissue accumulation of these advanced glycation end-products (AGEs) causes oxidative stress and pro-inflammatory signaling (Yan *et al.*, 1994). AGE removal and renal clearance are essential for tissue homeostasis, and are

mediated primarily by class J SRs, termed RAGE (receptors for AGE), seconded by SR-AI, CD36, LOX-1, and STAB1/FEEL-1 and 2 (Horiuchi *et al.*, 2003). Binding to clearance receptors is a double-edged sword, as RAGE activates pro-inflammatory signaling and leads to more ligand generation and exacerbation of the disease (Schmidt *et al.*, 2001).

Like atherosclerosis, neurodegenerative diseases progress through a combination of chronic inflammation, ligand generation, and SR-mediated clearance and immune signaling. CD36 expressed on microglia mediates adhesion to β -amyloid deposits, which triggers pro-inflammatory cytokine and reactive oxygen species release, which further exacerbates neurodegeneration (El Khoury *et al.*, 1996, 2003). CD36 acts together in a receptor complex with integrins which enhances microglial adhesion to amyloid fibrils (Bamberger *et al.*, 2003). Ideally, microglia clear accumulating amyloid before plaques assemble, but the clearance receptors, including SR-AI, CD36, and RAGE, decline with age and exposure to a pro-inflammatory environment (Hickman *et al.*, 2008).

Receptor collaboration also underlies this sterile inflammation, as exemplified by CD36 cooperation with TLRs in response to oxLDL and amyloid- β . CD36 is required to endocytose ligands and assemble endosomal receptor-ligand complexes containing TLR4/TLR6 heterodimers (Stewart *et al.*, 2010). In addition to activating endosomal TLRs, CD36 (and to a lesser extent, SR-A, which binds the same ligands) promotes ligand aggregation in endosomes, and the resulting cholesterol crystals or amyloid fibrils destabilize lysosomal membranes and trigger NLRP3 inflammasome activation in the cytosol (Sheedy *et al.*, 2013).

SRs as Causes and Therapeutic Targets in Disease

SRs in Metabolic Disease Association Studies

Given their prominent role in oxidized lipoprotein uptake and macrophage foam cell formation, SRs are candidate risk genes for cardiovascular disease and metabolic syndrome. Redundancy in oxLDL uptake mechanisms however means that single SR loci have so far failed to reach significance in genome-wide association studies.

SR-BI is involved in reverse cholesterol transport, consisting in the removal of cholesterol from foamy macrophages in peripheral arteries, loading onto circulating lipoproteins and reuptake in the liver with subsequent excretion through the bile (Tall, 1998). Although SR-BI promotes cholesterol efflux from macrophages *in vitro*, the main efflux receptors on vascular macrophages *in vivo* are ABC transporters ABCA1 and ABCG1 (Wang *et al.*, 2007b). SR-BI is athero-protective through its contribution in the liver, where it helps to absorb cholesterol from the circulation (Varban *et al.*, 1998). Accordingly, a host of studies, both large-scale and targeted to families with altered lipid profiles, have found polymorphisms in SR-BI to be associated with variations in plasma high-density lipoprotein (HDL) cholesterol levels (Osgood *et al.*, 2003; Tai *et al.*, 2003; Teslovich *et al.*, 2010; McCarthy *et al.*, 2003; Roberts *et al.*, 2007). A SNP (rs10846744) in SR-BI is predictive of cardiovascular events across ethnicities (Naj *et al.*, 2010; Manichaikul *et al.*, 2012). Additional SNPs correlate well with the

pleiotropic effects of SR-BI in steroid hormone metabolism, fertility, and platelet function (Chadwick and Sahoo, 2013).

CD36 deficiency, also called Platelet glycoprotein IV deficiency as CD36 was originally identified as a platelet surface molecule, frequently affects Asian and African populations, and causes cardiomyopathies (Hirano *et al.*, 2003). As CD36 is a transporter for long-chain fatty acids, which are a major energy source for the heart muscle, patients that lack CD36 develop heart muscle failure. Additional abnormalities in fatty acid metabolism cause defects in lipid distribution and insulin resistance, commonly termed 'metabolic syndrome.' Unsurprisingly, CD36 polymorphisms therefore also associate with type 2 diabetes in population studies (Banerjee *et al.*, 2010; Gautam *et al.*, 2013). The geographical prevalence of CD36 deficiency may be linked to its role in immunity, in particular, interactions with *M. tuberculosis* and *Plasmodium*-infected erythrocytes. Tuberculosis and malaria affect geographical areas where CD36 deficiency is prevalent, but whether mutations are under selection by infectious diseases is so far unclear (Fry *et al.*, 2009; Aitman *et al.*, 2000).

SRs in Cancer

Germline mutations and variants in SR-AI are associated with increased risk for prostate cancer (Xu *et al.*, 2002), and for Barrett's esophagus, an acid reflux condition leading to esophageal cancer (Orloff *et al.*, 2011). While it is unclear by which mechanism SR-A predisposes to development of these specific types of cancer, a relevant starting point may be the observation that SR-A is upregulated on tumor-associated macrophages (TAMs), and that SR-A on TAMs is a pro-oncogenic driver in tumor cell-macrophage cross-talk (Hagemann *et al.*, 2006). This has been successfully exploited to target a toxin to SR-A expressing TAMs and prevent tumor progression in a mouse model of ovarian cancer. Similarly, blocking SR-A by small peptide mimetics of SR-A ligands in the same model seems to interfere with pro-oncogenic TAM-tumor cell cross-talk and halt metastasis (Neyen *et al.*, 2013b). The pro-oncogenic role of SR-A might however be tumor-type or environment specific as studies in lung tumorigenesis report an association between SNPs lowering SR-A expression and bad prognosis (Ben *et al.*, 2012). An interesting link to investigate would be the prominent contribution of class A SRs to detection of environmental irritants in the lung.

For class A member SCARA5 pro-oncogenic mechanisms are clearer: identified in a human genome-wide screen for candidate tumor suppressor genes, SCARA5 is involved in maintaining adhesion signaling in normal cells. SCARA5 down-regulation in tumor cells licenses focal adhesion kinase signaling and promotes metastasis (Huang *et al.*, 2010).

A comprehensive survey of SR expression levels in lymph node sinusoidal cells shows distinct but overlapping profiles of SRs on epithelial cells and macrophages, suggesting a variety of retention mechanisms for metastatic tumor cells within lymph nodes (Martens *et al.*, 2006). Metastasis relies in part on the ability of tumor cells to adhere to extracellular matrix and leave the circulation. Hyaluronic acid prevents tumor metastasis, but is efficiently cleared from the circulation by STAB1 and 2. Two promising antitumor strategies target STAB1

interaction with hyaluronan. Antibody-mediated blocking of STAB1 resulted in elevated hyaluronan in circulation and decreased metastasis in a murine model of metastatic melanoma (Hirose *et al.*, 2012). In a murine prostate cancer model, the same approach decreased interaction between sinusoidal epithelium and tumor cells mediated by their pericellular hyaluronan matrix (Simpson *et al.*, 2012).

Taken together, these examples suggest that the main role of SRs in tumorigenesis is probably to be found in oncogenic misappropriation of physiological roles in cell–cell and cell–matrix adhesion.

Rare Monogenic Diseases Attributed to SRs

Since many SRs are functionally redundant, it may be unsurprising that lack-of-function mutations in SR genes rarely give striking phenotypes. However, some rare deficiencies give insight into gene-exclusive roles for select SRs.

Rare mutations in the class B member SCARB2/LIMP2 cause myoclonic epilepsy and renal failure at an early adult age. The underlying pathology derives from incorrect targeting of the lysosomal enzyme β -glucocerebrosidase, which is chaperoned by SCARB2 in normal cells. In the absence of functional receptor, unprocessed enzyme substrate accumulates in lysosomes (see Section Multiple SRs Mediate Clearance of Normal Self; Dardis *et al.*, 2009).

Lack of class F SCARF2/SREC-II causes a rare autosomal recessive disorder called Van Den Ende–Gupta syndrome, which is characterized by skeletal abnormalities that do not affect intelligence and are not life-threatening (Anastasio *et al.*, 2010). The fact that this deficiency is not compensated by other SRs points toward a critical role of SCARF2 in epidermal differentiation and bone morphogenesis during development.

SRs as Therapeutic Targets

Beyond the oncostatic approaches above, SR-based therapies are generally harnessing the myeloid-restricted expression of SRs to target macrophages in disease contexts. In particular, SRs are highly expressed on macrophages and smooth muscle cells in atherosclerotic plaques but not in healthy arteries, and are highly efficient in internalizing ligands. These properties can be exploited to target ligand-coated nanoparticles to macrophage-rich atherosclerotic lesions, to improve their contrast on magnetic resonance imaging (MRI) scans and allow better predictive assessment of plaque stability (Lipinski *et al.*, 2004). One approach successfully applied in atherosclerotic mice used iron oxide nanoparticles coated with ligands for SR-AI, for example, dextran sulfate or an SR-AI reactive peptide (Segers *et al.*, 2013; Tu *et al.*, 2011). Another approach enclosed the contrast agent gadolinium in phospholipid micelles coated with anti-SR-A antibodies which directed uptake into macrophages and improved plaque contrast in MRI (Amirbekian *et al.*, 2007). The advantage of lipid micelles or liposomes is their versatility in delivering cargo. In addition to contrast agents for MRI, a cargo of choice are chemotherapeutic agents targeted to TAMs (Rensen *et al.*, 2006; Etzerodt *et al.*, 2012). An exciting new avenue has opened up with the discovery of naturally occurring transport

of microRNAs on circulating lipid-based carriers (Vickers and Remaley, 2012). In particular, HDL carrying miRNAs is delivered to SR-BI expressing cells and effects gene expression changes in target cells (Tabet *et al.*, 2014; Vickers *et al.*, 2011).

Another class of therapeutic molecules targeting SRs are BLTs (Blocker of Lipid Transport), small molecule inhibitors which block selective cholesterol uptake by occupying the lipid channel in class B receptors (Niemand *et al.*, 2008, 2013). Beyond their obvious applications in modulating cholesterol transport, BLTs have been applied to other SR-B-dependent etiologies. BLT-1, 2, and 4 can block *Plasmodium* sporozoite infection of human hepatocytes in culture, by interfering with parasite docking to SR-BI (Rodrigues *et al.*, 2008). Similarly, HCV uses SR-BI as a co-receptor to infect hepatocytes, and BLT-2 and 4 are efficient in blocking HDL-aided HCV entry into hepatocytes (Bartosch *et al.*, 2005; Voisset *et al.*, 2005).

Finally, class A and B SRs are able to bind to small apolipoproteins A and E which share an amphipathic α -helical structure and perform athero-protective functions (Williams *et al.*, 2000; Neyen *et al.*, 2009). Small peptides that mimic this amphipathic helical structure are versatile therapeutics with a broad range of applications (Navab *et al.*, 2006), some of which specifically target SRs. The apo A-I mimetic D4F blocks SR-A function in tumor cell–macrophage cross-talk and prevents metastasis of ovarian and pancreatic cancer cells in a murine model (Neyen *et al.*, 2013b). Like BLTs, apo E peptide mimetics block access of HCV to SR-BI (Liu *et al.*, 2012), and a similarly structured peptide blocks LPS binding to and internalization by SR-BI, preventing downstream pro-inflammatory signaling (Bocharov *et al.*, 2004). Administration of apoAI or apoE mimetic peptides to murine models of neurodegenerative disease reduces brain inflammation and microglial accumulation (Handattu *et al.*, 2009, 2013). Although a direct action of peptides on microglial adhesion through SRs is not proven, it remains a tempting mechanistic explanation.

In summary, understanding the multifaceted biology of SRs in homeostasis and disease is expected to yield future advances in therapy, particularly in macrophage-driven inflammatory diseases.

Discovery of Dendritic Cells

In search of the cells that initiate immune response, Steinman and colleagues discovered dendritic cells (DCs) using morphology-based method. DCs are shown to be the most potent initiator of T cell immune response comparing to other cells. DC-specific monoclonal antibodies were made and enabled characterization and easy isolation of DCs. DCs form a wide network of antigen capture, transport and presentation. Many subsets of DCs collaboratively orchestrate immune response.

Identification and Isolation

The discovery of DCs was the result of an effort to understand the initiation of immunity. In 1967, Mishell and Dutton developed an *in vitro* priming system in which mouse spleen cell suspensions could be stimulated to generate antibody responses in culture (Mishell and Dutton, 1967). It was quickly observed that lymphocytes alone were not sufficient to induce antibody forming cell responses, and that an adherent accessory cell, or antigen presenting cell (APC), was required. At the time, macrophages were thought to be the key accessory cell because they composed a major population of adherent cells and also because their role in innate immunity had been long appreciated (Unanue and Cerottini, 1970). However, macrophages failed to show robust activity in induction of antibody responses *in vitro*, and they rapidly digested ingested antigen suggesting that they would be unable to present it to lymphocytes (Ehrenreich and Cohn, 1969, 1967; Steinman and Cohn, 1972).

Speculating that another cell type distinct from macrophage initiates immune response, Steinman and Cohn examined spleen adherent cells by phase contrast microscopy; they discovered a small population of cells with stellate shape and named them DC (Steinman and Cohn, 1973). They then employed physical techniques to fractionate spleen cells and purify DCs. DCs were found to adhere to plastic or glass, had low buoyant density, and did not bind to erythrocytes coated with antibody. Comparing to macrophages that contain abundant lysosomes in the cytoplasm and are actively phagocytosing, DCs contain few lysosome and are weaker in phagocytosis.

The original evidence of DCs' immunogenicity came from two crucial experiments. First, in an *in vitro* model system to study graft rejection, i.e., mixed leukocyte reaction, DCs were nearly two orders of magnitude more potent than unfractionated spleen cells, B cells or macrophages in stimulating allogeneic T cells (Steinman and Witmer, 1978; Nussenzweig and Steinman, 1980). This effect is attributed to abundant allogeneic MHC II on DC surface, which does not require priming. Second, in a coculture system with syngeneic responding T cells and hapten-modified thymocytes, DCs induced MHC-restricted cytotoxic T cells specific to the hapten;

in contrast, macrophages and other purified populations of lymphoid cells were nearly inactive as accessory cells (Nussenzweig *et al.*, 1980). Thus DCs were discovered as the most potent APCs to initiate T cell immunity.

Distribution of DCs

Sequential steps of density centrifugation in bovine serum albumin gradients and adherence to glass were originally used to purify DCs (Steinman and Cohn, 1974). Immunization with these purified DCs led to production of a series of DC-specific antibodies in 70–80s, including 33D1, NLDC and N418. These antibodies made it possible to characterize DC distribution *in vivo* with immunohistochemistry. DCs are widely distributed in most organs, a distribution that maximizes antigen capture and subsequent induction of T cell response.

DCs in lymphoid organs

DCs are found in the central lymphoid organs, bone marrow and thymus. In the bone marrow, DCs are organized into perivascular clusters that enveloped blood vessels. These bone marrow DCs contribute to promoting the survival of mature B cells that home back to the bone marrow. In the thymus, DCs reside in thymic cortical epithelium and thymic medulla. Thymus is where T cells mature through positive and negative selection. Thymic DCs mediate central tolerance, through negative selection or clonal elimination of T cells that are self-reactive, and induction of regulatory T cells that suppress self-reactive T cells.

DCs reside in the peripheral lymphoid organs, spleen and lymph nodes, where immune response is initiated. Naïve T cells circulate through T cell areas in spleen and lymph nodes. In these areas, DCs are enmeshed in an extensive network and they are actively probing adjacent T cells with their processes, a crucial scanning step preceding T cell clonal expansion.

DCs in non-lymphoid organs

DCs are also found in most non-lymphoid organs and in all epithelial surfaces that contact the environment. In organs such as heart, lung, kidney, the dermal layer of skin, and meninges and choroid plexus in the brain, they are found in interstitial spaces that are drained by lymphatics. In skin, the epidermal layer contains Langerhans cell expressing Fc receptors and MHC class II, capable of presenting antigen to primed T cells; the dermal layer of skin is also populated with DCs. Epidermal Langerhans cell and dermal DCs have different origin, but both appear to function as DCs, i.e., present antigen and activate T cells. DCs are also found in all stratified squamous epithelia such as the vagina, cervix, anus, pharynx, and esophagus as well as in other epithelia, as in the airways of the lung, the intestine, and the iris and ciliary body.

DC migration

Migration of DCs from peripheral tissues into lymphoid organs is key to their sentinel and antigen trafficking functions. Upon microbial contact or stimulation by inflammatory cytokines, resident DCs from non-lymphoid tissue traffic through afferent lymphatics to the lymph node T cell areas, where they participate in the initiation of immune responses. For example, elicitation of allergic contact dermatitis and immunity induced by HSV or Leishmania requires interaction of antigen with epidermal Langerhans cells or dermal DCs respectively, followed by migration of these DCs to the lymph nodes to present antigen to T lymphocytes.

Even in the absence of invading pathogens, some DCs are always migrating from tissues to lymph nodes through afferent lymph. Most of the migrating DCs die after their arrival in lymphoid tissues, thus DCs are not detectable in the efferent lymph. The DCs that migrate in the steady state might have several functions: to replenish immature populations, to transport self or environmental antigens, or to be on patrol to identify invaders.

DC migration is a regulated process, controlled at the level of chemokine production and chemokine receptor expression and function. CCR7 and its ligands CCL19 and CCL21 are essential for DC migration, both in the steady state and during inflammation (reviewed in [Randolph et al., 2005](#)). Chemokine/chemokine receptor interactions not only orchestrate DCs' migration but also influence their immunogenic potential.

Therefore, DCs in the peripheral tissue and lymphoid organs form a vast network. Migration of DCs enables antigen captured in the periphery to be transported to the lymphoid organ, where they are presented to T cells for initiation of tolerance and immunity.

DC Subsets

In each organ, DCs are heterogeneous and comprised of multiple groups and subsets ([Ardavin and Shortman, 1992](#); [Vremec et al., 1992](#)). These groups differ in their anatomic distribution, cell surface marker expression and function. In the mouse, three major groups of DCs exist in the steady state: plasmacytoid DCs (pDCs), conventional DCs (cDCs), and migratory DCs (mDCs). Under inflammation, a new population of DCs arises from monocytes (mo-DCs).

pDCs

pDCs, marked by the expression of B220 and PDCA1 and their morphological resemblance of plasma cells, are important mediators of antiviral immunity through their ability to produce large amounts of type I interferons (IFNs) on viral infection (see below).

cDCs

cDCs are composed of two major subsets, namely $CD8\alpha^+$ and $CD11b^+$ cDCs ([Shortman and Liu, 2002](#)). They have overlapping functions; both can process and present antigens to T cells; both subsets also secrete cytokines such as IL-12, which can inform the ultimate polarization of the T cell response to pathogens. However, the two subsets also have distinct anatomic localization and functions *in vivo* and are not redundant.

For example, in mouse spleen, $CD8\alpha^+$ cDCs localize to T cell areas and specialize in priming $CD8^+$ T cells, whereas $CD11b^+$ cDCs localize to the bridging channel and specialize in priming $CD4^+$ T cells.

mDCs

mDCs are present in non-lymphoid tissues such as the liver, gut, skin, lung, and aorta, and they too are composed of two main subsets $CD103^+$ and $CD103^-$ DCs (reviewed in [Helft et al., 2010](#)). These non-lymphoid DCs are referred to as mDCs because they transit from tissue to lymphoid organs (reviewed in [Banchereau and Steinman, 1998](#); [Shortman and Liu, 2002](#)). $CD103^+$ tissue DCs are developmentally related to $CD8\alpha^+$ cDCs.

Mo-DCs

Under inflammation, a new subset of DCs arise from monocytes (mo-DCs). For example, upon infection of *Listeria monocytogene*, increased CCL2 drives CCR2-expressing monocytes to emigrate from bone marrow, upregulate CD11c and MHC II on cell surface and differentiate to mo-DCs. Upon entering the infection sites, mo-DCs produce TNF- α and iNOS which confer innate protection. Therefore, another name for monocyte-derived DC (mo-DC) is TNF- α , iNOS-producing DCs (Tip-DCs). In CCR2 $^{-/-}$ mice, monocytes failed to migrate, rendering the mice highly susceptible to *Listeria* infection.

Gene expression comparison, selective targeting and depletion of specific subset *in vivo* reveal that DC subsets have distinct features and functions. They differ in expression of cell surface and cytoplasmic receptors for detecting pathogens, antigen processing capacity, and ability to produce cytokines and chemokines. For example, $CD8\alpha^+$ cDC and their developmentally related $CD103^+$ non-lymphoid DCs are uniquely potent and indispensable in cross-presenting antigens on MHC I and initiate $CD8^+$ T cell immunity against tumor, virus and intracellular pathogen.

In conclusion, multiple subsets of DCs have distinct micro-anatomical locations, gene expression profiles and functions. Collaboratively, these DCs orchestrate immune response.

DC Development and Homeostasis

Growth Factors and DC Cultures

DCs only constitute less than 2% of hematopoietic cells *in vivo*. Therefore, *in vitro* culture systems were established to produce human and mouse DCs in large number; these culture systems are widely used today for basic and clinical studies. Bone marrow cells from mice or peripheral blood monocytes from humans are cultured for 6 days in medium containing GM-CSF to produce cells with dendritic morphology that exhibit modest phagocytic activity, express CD11c and MHC II, and stimulate the MLR. Differentiation and activation can be further stimulated by addition of LPS, which activates DCs rendering them more immunogenic. Notably, GM-CSF is dispensable for DC development *in vivo* in the steady state; DCs generated in GM-CSF culture are more closely related to mo-DC than to the authentic cDCs in the lymphoid organs in the steady state.

Authentic cDCs can be produced *in vitro* using cultures of mouse bone marrow cells supplemented with Flt3L (Naik *et al.*, 2005). Flt3L cultures produce all of the known subsets of DCs, including cells with features of pDCs, CD8a⁺/CD103⁺ and CD11b⁺ cDCs (Naik *et al.*, 2005). Flt3L is indispensable for normal DC development *in vivo*. In mice deficient in either Flt3L or its receptor Flt3, DC development is impaired (Waskow *et al.*, 2008; McKenna *et al.*, 2000). Consistent with these observations, administration or over-expression of Flt3L results in selective expansion of DC populations, including fully differentiated DCs in lymphoid organs (Waskow *et al.*, 2008; Maraskovsky *et al.*, 1996). Moreover, human cDCs can be obtained from cultures of human cord blood supplemented with Flt3L and GM-CSF (Poulin *et al.*, 2010), although this culture does not produce human pDCs.

Cellular Origin

Inflammation stimulates monocyte differentiation to DCs

Monocytes were long thought to be the major progenitor of cDCs. However, direct transfer experiments and genetic experiments prove that most cDCs in the steady state peripheral lymphoid organs do not descend from monocytes (Jakubzick *et al.*, 2008). Monocytes only differentiate to DCs under inflammation. This was observed with injection of CFA or LPS, or infection with pathogens. Thus although monocytes can develop some of the features of DCs under conditions of inflammation *in vivo*, or when cultured with cytokines *in vitro*, but they are not precursors of cDCs in the steady state.

DC progenitors in the bone marrow

HSCs give rise to common lymphoid progenitors (CLPs) and common myeloid progenitors (CMPs). It is widely accepted that DCs descend from the Flt3 (CD135)-expressing CMPs. These CMPs then progress to a common precursor for monocytes, macrophages and DCs (macrophage-DC progenitors, MDP). MDP are defined as Lin[−] CX3CR1⁺ CD11b[−] CD115⁺ cKit⁺ CD135⁺ and account for 0.5% of all BM mononuclear cells in mice (Fogg *et al.*, 2006; Waskow *et al.*, 2008). Comparing to CMP, MDP has minimal potential to produce granulocytes, but can produce monocytes, pDCs, and cDCs. MDP then progresses to common DC progenitor (CDP). CDP, defined as Lin[−] CD115⁺ Flt3⁺ CD117^{lo}, produces cDCs and pDCs but not monocytes *in vitro* (Naik *et al.*, 2007) or *in vivo* (Onai *et al.*, 2007). Therefore the split between the monocyte and DC lineages occurs in the bone marrow between the MDP and CDP stages of development (Liu *et al.*, 2009).

Migratory pre-DCs

cDC precursors must migrate from the bone marrow to the lymphoid organs through the blood. However, MDP and CDP are restricted to the bone marrow (Liu *et al.*, 2009). A precursor with the potential to produce cDCs (pre-DC) was identified as CD11c⁺ MHC II[−] Flt3⁺ SIRPα^{lo} cells in the blood, bone marrow and periphery of mice (Del Hoyo *et al.*, 2002; Diao *et al.*, 2004; Naik *et al.*, 2006; Liu *et al.*, 2009). Pre-DCs descend from CDPs, migrate from the bone marrow to the blood and then to peripheral lymphoid organs and non-lymphoid tissues (Liu

et al., 2009). Pre-DCs have a short half-life in the blood of less than 1 h (Liu *et al.*, 2007), and comprise ~0.5% of all leukocytes in bone marrow, 0.02% in blood, 0.05% in the spleen and 0.03% in the lymph nodes respectively. The constant output of pre-DC from the bone marrow is essential for replenishment of DCs in the periphery.

In conclusion, in mice, the DC and monocyte lineages split in the bone marrow, where MDPs give rise to both monocytes and CDP; the latter produces pre-DCs, which migrate from BM through the blood to the periphery to give rise to DCs (Figure 1). Corresponding to the crucial dependence of Flt3L for DC development, expression of Flt3 is retained throughout the natural history of DC development (Karsunky *et al.*, 2003; Liu *et al.*, 2009).

Transcriptional regulation of DC development

A number of different transcription factors are known to regulate DC development. These factors include PU.1, STAT3, Gfi1, E2-2, Id2, Batf3, and RBP-J. These factors are part of a yet to be defined program that turns on expression of lineage-specific genes, and suppress alternative developmental programs, regulating differentiation at different stages or of unique DC subset. The function of each factor is reflected by change of number or subset of DC in corresponding genetic models. These models proved important in investigating the function of DC and DC subsets in various immune responses. For instance, experiments using Batf3^{−/−} mice that specifically lack CD8a⁺ and CD103⁺ DC prove the essential role of such DCs in activating CD8 T cell against tumor, virus and intracellular pathogens (reviewed in Murphy, 2013).

Human DC Development

Three different subsets of DCs have been found in human blood. These subsets are referred to as BDCA1 (CD1c), BDCA2 (CD303), and BDCA3 (CD141) DCs based on their expression of cell surface markers (reviewed in Collin *et al.*, 2011). It is widely accepted that BDCA1⁺ DCs resemble mouse CD11b⁺ cDCs; BDCA2⁺ CD11c[−] DCs are equivalent to mouse pDCs; BDCA3⁺ DCs are equivalent to mouse CD8a⁺ cDCs (Figure 2). These interspecies associations were initially based on similarities in gene expression between human and mouse DC subsets (Robbins *et al.*, 2008), and were supported by functional experiments (Croizat *et al.*, 2010; Poulin *et al.*, 2010; Lauterbach *et al.*, 2010).

The human equivalents of the bone marrow derived DC precursors, MDP, CDP, and pre-DC remain to be isolated. However, recent clinical studies revealed genetically defined syndromes associated with DC deficiency that shed some light on human DC development. Several different genetic lesions have been associated with the triad of DC deficiency, monocytopenia and opportunistic infections. GATA2 mutation leads to a loss of DC, monocytes, B and NK cells (DCML). IRF8 mutation is associated with disseminated bacille Calmette-Guérin (BCG) infection (Hambleton *et al.*, 2011). Loss of DCs due to IRF8 mutation also leads to myeloproliferation in humans due to increased serum Flt3L, which induces expansion of myeloid progenitors. Elucidation of cellular and molecular mechanisms underlying aberrant human DC

Figure 1 DC origin and development.

Figure 2 Functionally correlated DC subsets in human and mouse.

development will require identification of restricted DC progenitors in human (reviewed in Collin *et al.*, 2011).

DC Homeostasis and Regulation

The half-life of cDCs in mouse tissues was measured in parabionts and shown to vary from five to seven days in the spleen, lymph nodes, liver and kidney and as many as 25 days in the lung (Liu *et al.*, 2007; Ginhoux *et al.*, 2009). cDC homeostasis in all organs is maintained through a dynamic balance of three parameters: continuous input of pre-DCs from the blood, limited cDC division *in situ* and cell death. Fitting the BrdU incorporation data and the parabiosis separation data into the equations produced a numerical estimate of the rate of DC precursor input ($\sim 4300/\text{hour}$) and DC death ($\sim 9600/\text{hour}$) in the mouse spleen (Liu *et al.*, 2007).

cDCs in mouse lymphoid and non-lymphoid tissues divide *in situ* for 10–14 days before being replaced by pre-DCs (Liu *et al.*, 2007). Division of DCs is regulated by Flt3L and lymphotoxin-beta ($\text{LT}\beta$). Flt3L impacts nearly all stages of cDC development including early hematopoiesis in the bone marrow and division in the periphery (Waskow *et al.*, 2008; Maraskovsky *et al.*, 1996; Kingston *et al.*, 2009). Increased production of Flt3L, for example, during malaria infection (Guermónprez *et al.*, 2013) leads to increase of DC progenitor proliferation in the bone marrow and DC division in the periphery. In contrast, the effects of $\text{LT}\beta$ appear to be limited to $\text{CD11b}^+ \text{CD4}^+$ spleen DCs (Kabashima *et al.*, 2005).

Tregs also exert an effect on DC division. A feedback loop between DCs and Tregs maintains the physiologic numbers of these two cell types in the steady state. Loss of Tregs leads to activation of T cells, which induces DC division via Flt3L. Conversely, increasing the number of DCs by Flt3L injection leads to an increase in the number of Treg cells (Figure 3). Alterations in this mechanism lead to immune imbalance and can alter the course of autoimmune disease in mice (reviewed in Liu and Nussenzweig, 2010). Thus, the Flt3L-mediated homeostatic feedback loop between Treg and DCs has clinical implication for vaccine design, as well as the control of auto-immunity. Finally, this mechanism is entirely consistent with the proposed role of DCs in maintaining tolerance and regulating immunologic responses *in vivo* (Steinman and Nussenzweig, 2002).

Features Enable DCs as the Orchestrator of Immunity

DCs are crucial immune sentinels. First, DCs detect danger signals associated with infection, produce cytokines to alarm the immune system and activate other innate cells to confer

protection. Second, armed with unique cellular feature, DCs effectively capture, process and present antigens to initiate adaptive T cell immune response. Third, in response to the signal associated with the antigens, DCs adjust activation or maturation status, as such directing either immunity to pathogenic antigens or tolerance to harmless antigens. Thus DCs bridge innate and adaptive immune response, and control the quality of adaptive immune response toward either tolerance or immunity of different types.

DCs in Innate Immunity

Innate pDCs

One DC subset with prominent innate activity is pDC, which specializes in rapidly producing type I interferon upon detecting infection. pDCs selectively express TLR7 (single-stranded RNA sensor) and TLR9 (DNA sensor), both of which reside in the endosomal compartment. pDCs endocytose viruses, and sense their nucleic acids using TLR7 and TLR9. Viruses that enter the cytoplasm of pDCs are detected after autophagy, a conserved cell-autonomous process involving lysosomal degradation of cellular organelles to deliver cytoplasmic RNA to TLR7-containing endosomal compartments. Upon binding of ligands, TLR7 and TLR9 recruit MyD88. This results in assembly of a signal-transducing complex that includes IRAK4, TRAF6, Bruton's tyrosine kinase (BTK) and IRF7 leading to type I IFN production. In pDCs, constitutive expression of IRF7 enables a rapid production of type I IFN. Type I IFN produced from activated pDC not only directly inhibits viral replication, but also activates NK, B cells and cDCs (Blanco *et al.*, 2001). Activation of pDC and production of type I IFN is tightly regulated by feedback inhibition. Constitutive activation of pDC and overproduction of type I IFN are at the center of pathogenic inflammation in autoimmune diseases such as systemic lupus erythematosus.

Activation of innate lymphocytes

Another aspect of innate role of DCs is activation of innate lymphocytes (e.g., NK, NKT and ILCs). Besides pDCs, other DC subsets express TLRs, recognize PAMP and become activated. Different function of cDC subsets may be partly attributed to differential expression of Toll like receptors (TLRs). For example, spleen CD8a^+ cDCs in mouse and BDCA3^+ DCs in humans express TLR3 but lack TLR5 and TLR7; when stimulated with virus with double strand virus or PolyI:C, a ligand for TLR3, they produce IFN α and IL-12. CD11b^+ cDCs express TLR5 and TLR7 but low amount of TLR3 (Edwards *et al.*, 2003). DC activation leads to the recruitment of NK cells into the draining lymph nodes; activated DC also produce IL-12, IL-15 and IL-2, which in turn activate NK cells to produce IFN- γ . DCs activate NKT cells by presenting glycolipids on CD1d molecules to the invariant T cell receptor on NKT cells *in vivo* (reviewed in Munz *et al.*, 2005). Another recently defined type of innate cells that can be activated by DCs are innate lymphoid cells (ILCs), lymphocytes that lack recombined antigen-recognition receptors that are dependent on the transcription factor ID2 for their development. Interestingly, distinct DC subsets activate different subsets of ILC. CD8a^+ DCs control ILC1s, which are functionally similar to

Figure 3 Homeostatic feedback loop between DCs and Treg cells.

but developmentally distinct from NK cells; CD11b⁺ DCs control ILC3s, including lymphoid tissue inducer (LTi) cells, CD4⁺ LTi-like cells, and NKp46⁺ cells, all of which are developmentally dependent on ROR γ t. Upon bacterial sensing, CD11b⁺ DCs produce IL-23, which consequently activates ILC3s to produce IL-22 (reviewed in [Briseno et al., 2014](#)).

Antigen Capture, Processing and Presentation

Antigen capture

Macropinocytosis

DCs in culture continuously form 0.25 to 1.0 μ m pinocytic vesicles. It is believed that DCs *in vivo* also use these vesicles to sample a large volume of extracellular fluid and soluble proteins that are present at low concentrations.

Receptor mediated phagocytosis

Multiple receptors on cDCs enhance recognition and ingestion of particulates including pathogens and dying cells. Some of the receptors recognize molecular patterns on pathogens and activate DCs, whereas others may lead to inhibition. For example, DCs express Fc receptors that mediate ingestion of opsonized particles and deliver them to intracellular compartments that facilitate cross-presentation to CD8 T cells. Fc receptors on DCs include both activating and inhibitory forms ([Muta et al., 1994](#)). The inhibitory receptors help DCs to maintain an immature tolerogenic state. In addition, DCs express many different types of pattern recognition receptors including the SIGN (specific ICAM-3-grabbing nonintegrin) family, and multiple C-type lectins such as macrophage mannose receptor (MMR), DEC205, and DCIR2. MMR binds a range of bacteria, yeasts, and viruses through interactions between a mannose-type carbohydrate recognition domain and pathogen-associated high mannose structures. These SIGN family receptors appear redundant, as deficiency of any single receptor confers no detectable susceptibility to pathogens.

Antigen processing

DCs and macrophages differ in their capacity to digest antigens. Macrophages endocytose antigens and rapidly digest them. In contrast, DCs sequester and preserve the captured antigen for later presentation. Preservation of antigens is critical for immunogenicity and is attributed to two features of DC lysosomes. The first is the low lysosomal protease activity. Macrophages contain high levels of lysosomal proteases, enabling rapid degradation of internalized proteins to single amino acids. In stark contrast, DCs express low amount of proteases, resulting in a limited capacity for lysosomal degradation ([Delamarre et al., 2005](#)). This low level proteolytic capacity is crucial since the peptides loaded on MHC and recognized by T cells must consist of peptides between 8 and 17 amino acids. A second feature is that DC lysosomes are less acidic than those in professional phagocytes. DC lysosome is featured with an incomplete assembly of V-ATPase that results in proton 'leakage,' and an efficient recruitment of Nox2 in lysosome that results in consumption of protons. Altogether, these lead to alkalinization of the endocytic compartment ([Trombetta et al., 2003](#)). Therefore, the lower levels of proteolytic activity, and decreased acidity in endocytic

compartment lead to a decrease in the rate of antigen digestion and increased availability of partially processed peptides for loading on MHC. This unique feature of DCs may also help preserve the antigen during the migration of non-lymphoid tissue DCs from the site of antigen capture to the lymph nodes.

Antigen presentation

DCs initiate T cell immune response in the lymph nodes and spleen. DC-T cell interactions have now been studied in the living state with two-photon microscopy ([Shakhar et al., 2005](#)). DCs present antigen peptides on MHC I and MHC II and scan the TCRs on T cells that circulate through entering the lymph nodes via a brief interaction. When a TCR finds the cognate MHC-peptide, the TCR-bearing antigen specific T cells arrest on antigen presenting DCs, and this stable interaction lasts for at least 18 h. Such DC-T cell interaction leads to tolerance in the steady state, unless an activation signal such as TLR ligation triggers DCs to initiate immunity.

In conventional presentation pathway, exogenous antigens are presented on MHC II to CD4⁺ T cells, whereas endogenous antigens are presented on MHC I to CD8⁺ T cells. CD8⁺ T cells are critical for protective immunity against intracellular pathogens and malignant tumor cells. However, viruses that do not infect DCs and tumors are exogenous antigens to DCs. Importantly, DCs are efficient in presenting exogenous antigen on MHC I, an unconventional presentation path called 'cross-presentation'. After taking up the exogenous viral or tumor antigens, in the form of non-replicative virus or apoptotic cells, DCs present them on MHC I to prime CD8 T cells ([Albert et al., 1998](#)). In the absence DCs, mice are unable to process several different antigens through the exogenous pathway, indicating that DCs are the major cell type for cross-presentation to CD8⁺ T cells *in vivo*. Multiple receptors including FcR, Lox-1, CD205 and DNGR1 have been shown to mediate antigen uptake for cross-presentation. Batf3-dependent CD8a⁺ DCs in mice and their functional equivalent BDCA3⁺ DCs in humans excel in cross-presenting exogenous antigens ([Hildner et al., 2008](#); [Poulin et al., 2010](#); [Schreibelt et al., 2012](#)). Exogenous presentation or cross-presentation by CD8a⁺ DCs has proved essential for protective immunity against viruses and tumors.

DC Maturation

DCs link innate pathogen recognition to the adaptive immune response and direct immune response toward tolerance or immunity. This is made possible by the two functionally distinct and phenotypically different stages of DCs. In the steady state, DCs in most tissues are equipped to capture and present antigens to T cells, but the outcome of antigen presentation by steady state DCs is tolerance and not immunity. Steady state DCs express high levels of pattern recognition and activation receptors allowing them to sense changes in the environment, including pathogens and inflammatory cytokines. For example, PAMP and DAMP associated with microbes and viruses induce DC activation by engaging Toll-like receptors and cytoplasmic receptors that recognize pathogen patterns such as MDA-5, RIG-I and DDX41, and NOD-like receptors (NLRs). Activated NK,

NKT, and T cells stimulate DCs through direct cellular contact by ligation of CD40 on DCs. Type I interferon, produced by pDCs or non-hematopoietic cells upon invasion of microbes and virus, also effectively activate DCs. These signals, largely through the NF- κ B pathway, induce extensive differentiation of DC to a mature state, a state characterized by redistribution of MHC class II from intracellular compartments to the plasma membrane, increased levels of cell surface MHC and co-stimulatory molecules such as CD40, CD80, and CD86, as well as secretion of cytokines, such as IL-1 α , IL-6, TNF- α , IL-18 and IL-12, and chemokines. In the mature state, DCs initiate potent and specifically polarized T cell immune responses.

Controlling the Quality of the T Cell Response

DCs are involved in critical T cell fate decisions. In the presence of mature DCs producing IL-12 or interferons (as might occur when DCs are ligated by CD40L or infected with viruses), CD4⁺ T cells differentiate along a Th1 pathway for interferon- γ production. The latter in turn activates the antimicrobial activity of macrophages and promotes killer T cell differentiation. In the presence of exogenous IL-4, however, DCs induce T cells to differentiate into Th2 cells, which secrete IL-4, IL-5 and IL-13. These cytokines help B cells to make antibodies of the IgG1 and IgE isotypes, activate eosinophils, and stimulate fibrosis. A new and striking pathway that was first discovered with human monocyte-derived DCs involves the epithelial derived cytokine, thymic stromal lymphopoietin (TSLP). This cytokine activates DCs to induce “inflammatory Th2 cells” which produce TNF α (rather than IL-10) in addition to IL-4, IL-5, and IL-13 (Soumelis *et al.*, 2002). DCs that are activated with either CD40L or TSLP are similar in appearance, being rich in MHC II and CD86 stimulatory molecules. However, they differ significantly in cytokine and chemokine production, and as mentioned, the functional consequences for T cells vary (Soumelis *et al.*, 2002).

DCs' Role in Tolerance

The fact that DCs can focus the immune response on antigens derived from the pathogen and avoid inducing immunity to self and environmental antigens critically depends on the immune tolerance to self and harmless antigens. DCs have a critical role in developing and maintaining immune tolerance.

Thymic DC contribute to central tolerance

Self-reactive thymocytes are deleted in the thymus by APCs during negative selection. Two major populations of APCs in thymus express MHC II, namely, medullary thymic epithelial cells (mTEC) and cDCs, and both are required for efficient negative selection. mTEC express a panoply of self-antigens under the control of the autoimmune regulator ‘AIRE’ (Anderson *et al.*, 2002). DCs capture self-antigens that enter the thymus through the blood stream and present them to self-reactive T cells to induce negative selection. In the absence of antigen presentation by DCs, negative selection of CD4⁺ thymocytes is impaired (Brockner *et al.*, 1997). In addition to negative selection, thymic cDCs also support the development of FoxP3⁺ Tregs (Proietto *et al.*, 2008). Thus, DCs contribute to central tolerance in the thymus by more than one mechanism.

DCs mediate peripheral tolerance

DCs also mediate tolerance in the periphery. Central tolerance is incomplete and in addition, the immune system must continually establish tolerance to harmless or ‘noninfectious’ antigen in the environment. The effective control of self-reactive T cells that have escaped central tolerance therefore depends on peripheral tolerance. DCs constantly carry innocuous antigens from the periphery, for example, from the skin, airways, stomach, intestine and pancreas and present them to T cells in lymphoid organs (reviewed in Steinman *et al.*, 2003b). In the steady state, antigen presented by immature DCs induce profound tolerance of T cells, even though these T cells can initially proliferate extensively to the antigen capturing DCs in the draining lymph nodes (Steinman *et al.*, 2003a). Mechanisms for peripheral tolerance can be intrinsic (deletion and anergy) or extrinsic (through regulatory T cells). B7 family members on the steady state DCs, for example, PD-L1 and CD86, can ligate the inhibitory molecules such as PD-1 and CTLA-4 on the T cells, leading to tolerance.

Controlling of regulatory T cells

Autoreactive T cells can remain quiescent in the presence of regulatory T cells. There are two types of Treg: naturally occurring Treg derived from thymus (natural Treg) and Treg induced from FoxP3⁺ CD4⁺ T cells in the periphery (induced Treg). DCs are able to employ environmental signals, vitamin A in the gut and vitamin D3 in the skin, to induce Treg and maintain tolerance to harmless foreign antigens. CD103⁺ DC subset in the gut and skin are particularly potent in inducing Tregs (Belkaid and Oldenhove, 2008). Activation of β -catenin is essential for DC to control Treg and peripheral tolerance.

DCs also maintain the homeostasis of Treg. Loss of DCs leads to a loss of Treg cells, and the remaining Treg cells exhibit decreased Foxp3 expression. Conversely, increasing the number of DCs leads to increased Treg cell division and accumulation by a mechanism that requires major histocompatibility complex II expression on DCs (Liu and Nussenzweig, 2010).

In sum, DCs have the capacity to induce and maintain tolerance by several mechanisms both in the central and peripheral lymphoid organs.

DCs in Clinical Immunology

Based on DC's role in immune response, it is not surprising that DCs play a pathogenic role in many diseases and become target in disease prevention and treatment.

DCs in Transplantation

In hematopoietic transplantation, recipient DCs initiate T-cell-induced graft versus host reactions. In organ transplantation, both donor and recipient DCs contribute to graft rejection.

DCs in Autoimmune Disease

Several human autoimmune diseases involve DCs. In rheumatoid arthritis, DCs in the synovial exudates produce TNF- α , contributing to the severity of the disease. In psoriasis,

lesional skin is populated with activated pDCs that produce type I IFN and mo-DCs that produce TNF- α and polarize T cells toward Th1/Th17 (Lowes *et al.*, 2005). In systemic lupus erythematosus (SLE) two subsets of DCs contribute to the onset and severity of the disease; pDCs in SLE patients overproduce IFN- α , which activates cDCs and interferes with their ability to maintain peripheral tolerance (Blanco *et al.*, 2001).

DCs in Viral Infections

DCs mediate antiviral immunity by priming T cell responses. However, a number of viruses have evolved strategies to subvert DCs and thereby the immune system. DCs carry HIV from peripheral tissues into draining lymph nodes, where the virus is transmitted to CD4 T cells. Transmission to CD4 T cells is dependent on DC-SIGN, a C-type lectin pathogen-recognition receptor expressed on the surface of DCs that retains the attached virus in an infectious state. Interestingly, DC-SIGN also serves as receptor for several other viruses, including hepatitis C virus, Ebola virus, cytomegalovirus, dengue virus, and the SARS coronavirus. Dengue virus targets DCs directly through DC-SIGN but also enters DCs as a passenger in the form of immune complexes that are taken up by Fc receptors. When infection occurs through antibody enhancement mediated by Fc receptor, the infected DCs are involved in induction of the T cell cytokines that mediate the vascular leak syndrome associated with the infection, causing hemorrhagic fever.

DCs in Cancer

Tumors can suppress immunity in part through their effects on DCs. DC differentiation and activation can be suppressed by cancer-derived cytokines such as IL-6, vascular endothelial growth factor, and IL-10. In contrast to their normal counterparts, which activate immune responses, DCs derived from tumors induce Tregs and suppress proliferation of CTL and natural killer T cells (NKT cells).

DC Targeted Vaccines

DC-based vaccines are currently being used in the clinic and DC targeted vaccines are being tested. In currently available DC-based immune therapy, monocyte-derived DCs are generated *ex vivo*, loaded with tumor cells or tumor antigens, and re-injected into the patient (Schuler-Thurner *et al.*, 2002). Scientific and practical problems exist with this approach, including limited responses possibly due to inefficient migration of monocyte-derived DCs from injection site to the draining lymphoid organs and inefficient antigen presentation.

DC targeted vaccines are based on the idea that antigens delivered specifically to DCs in conjunction with the appropriate adjuvants will produce strong and lasting immunity. The DC targeted vaccines require that antigens be delivered specifically to endocytic receptors on DCs, along with the appropriate stimuli to induce DC activation. For example, antigens have been incorporated into anti-receptor monoclonal antibodies, which are then injected into the vaccine recipient. In animal models, such *in vivo* DC-targeting has been shown to elicit immune responses that are broad, often generating

immunity against multiple epitopes. Potential DC targets include CD205, LOX-1/OLR1, MMR/CD206, DCIR/CLEC4A, DC-SIGN/CD209, DNGR1, langerin, and CD40 (reviewed in Steinman, 2011).

In summary, DCs play important roles in a number of different diseases. Moreover, they are excellent targets in designing new approaches to prevention and treatment of these diseases.

Introduction

Neutrophils are sentinel cells and are the first to arrive at sites of infection to defend the host from invading microbes. The bone marrow is the site of neutrophil production. Under conditions of homeostasis, neutrophils can be found in the bone marrow, lung, spleen, and liver. Typically, neutrophils have a very short half-life and therefore are produced at a rate of $5\text{--}10 \times 10^{10}$ cells day^{-1} to maintain steady-state. Neutrophil production is controlled by the synthesis of granulocyte-colony stimulating factor (G-CSF) in response to Interleukin-17A. During inflammation, the longevity of neutrophils increases to ensure their presence at sites of damage. Neutrophils that die by apoptosis at sites of inflammation are removed by phagocytic cells such as macrophages and dendritic cells. Neutrophils are non-mitotic cells and display a multilobulated nucleus, hence the alternative name of polymorphonuclear cells (PMNs) (Figure 1). In circulation, neutrophils remain in a resting state, which ensures their potent toxic arsenals are not accidentally released, damaging the host. They are recruited from the circulation to the tissue in response to microbes or other inflammatory stimuli. In tissue, they employ different mechanisms to damage pathogens. As such, significant decreases in neutrophils can lead to increased risk for severe infections (Klein, 2011), while tight regulation of these cells is crucial to prevent tissue injury.

This article summarizes important components of neutrophil biology, including their development and microbicidal mechanisms and their potential pathogenic role.

Neutrophil Development

Neutrophils originate in the bone marrow and enter the circulation as terminally differentiated cells. Various complex mechanisms and mediators are involved in the development of neutrophil precursors and in their terminal differentiation. Among them are cytokines, growth factors, microRNAs, and transcriptional regulation. Balance between the transcription factors C/EBP α (CCAAT/enhancer binding protein α) and PU.1 determine granulocytopoiesis commitment (Reddy *et al.*, 2002; Dahl *et al.*, 2003; Laslo *et al.*, 2006). C/EBP α regulates granulocytic differentiation by competing with the transcription factor NFI-A to modulate miR223 expression (Fazi *et al.*, 2005). Other important factors include Gfi-1 (growth factor independent-1) and C/EBP ϵ (Borregaard, 2010). Gfi-1 represses genes involved in proliferation of stem cells and monocyte-promoting transcription factors (Hock *et al.*, 2004; Zarebski *et al.*, 2008). Neutrophils arise from hematopoietic stem cells (HSC) and follow a regulated differentiation process as follows:

Figure 1 Neutrophil morphology. Neutrophils have distinct multilobulated nucleus with multiple granules covering their cytoplasm. Neutrophils isolated from a healthy volunteer express the granular protein LL-37 and cytosolic myosin-9. DNA was co-stained using Hoechst. Scale bar 10 μm .

Myeloblast

Myeloblasts have a diameter of 10–20 μm , are derived from HSCs and are normally found in the bone marrow. Morphologically, they are characterized by a large round to oval nucleus with a small basophilic cytoplasm with no evident granules. During the myeloblast stage, levels of C/EBP α gradually decrease (Bjerregaard *et al.*, 2003). The appearance of granules marks the transition from myeloblast to promyelocyte and C/EBP ϵ regulates the expression of granular proteins (Yamanaka *et al.*, 1997).

Promyelocyte

The morphology of the promyelocyte is similar to that of the myeloblast. Cells are larger and nuclei are round to oval with presence of nucleoli and diffuse chromatin distribution. The endoplasmic reticulum (ER) is more prominent and azurophilic granules (primary granules) accumulate in increasing numbers during this stage. These cells express CD33, CD13, and CD15 on cell surface and they differentiate into myelocytes.

Myelocyte

During this stage, secondary granules become evident in the cytoplasm. Nuclei are round to oval and eccentric, chromatin is coarse, and nucleoli are small. Formation of primary granules decreases, while secondary granules are small and numerous. CD14 and CD11b become present as surface markers during this stage.

Metamyelocyte

Metamyelocytes have a 'horseshoe-shape' nucleus without nucleoli. Chromatin is denser and cytoplasm is filled with primary, secondary, and tertiary granules (Quesenberry and Levitt, 1979; Lajtha *et al.*, 1953). ER becomes thinly dispersed.

Band (Juvenile)

Bands are characterized by further condensation of the chromatin, with a 'sausage-like' or band conformation. The nucleus is divided into two or more lobules connected by filamentous strands of heterochromatin. CD10 and CD16 markers distinguish bands from more immature forms.

Mature Neutrophils

The nucleus becomes more segmented (three to four lobules) indicating full maturation of the neutrophil, which exits the bone marrow and enters the circulation (Bainton *et al.*, 1971).

Granules are sequentially and continuously produced during granulocytic differentiation through vesicle budding from the Golgi apparatus. These compartments are classified into three distinct subsets:

1. Primary (azurophilic) granules appear during the promyelocyte stage. They are also known as peroxidase-positive granules and measure around 0.3 μm in diameter. Some

of the cargo proteins contained in these granules include defensins, bactericidal/permeability-increasing protein (BPI), neutrophil elastase, myeloperoxidase (MPO), proteinase 3 (PR3), and cathepsin G (Faurschou and Borregaard, 2003).

2. Secondary (specific) granules are synthesized during the myelocyte stage and have an approximate diameter of 0.1 μm . They are characterized by the presence of the glycoprotein lactoferrin and contain antimicrobial proteins such as neutrophil gelatinase-associated lipocalin (NGAL), human cationic antimicrobial protein (hCAP-18), and lysozyme (Faurschou and Borregaard, 2003).
3. Tertiary (gelatinase) granules appear during the band stage (Borregaard *et al.*, 1995; Borregaard and Cowland, 1997). They are smaller than specific granules and contain gelatinases such as leukolysin (matrix metalloproteinase (MMP)-25), MMP-8, and MMP-9.

Neutrophils also contain secretory vesicles that are synthesized during the last stage of maturation. Protein content is dictated by the transcriptional activity during the granule formation or by 'targeting by timing of biosynthesis' (Le Cabec *et al.*, 1996; Borregaard, 2010).

Neutrophil Migration into Sites of Inflammation

Once mature, neutrophils are released from the bone marrow in a tightly chemokine-regulated fashion (Geering and Simon, 2011). Chemokine receptors CXCR4 and CXCR2 play a critical role during neutrophil release from the bone marrow. Retention of mature neutrophils in the bone marrow is associated with mutations in CXCR4 or deletion of CXCR2 (Hernandez *et al.*, 2003; Eash *et al.*, 2009). Conversely, deletion of CXCR4 receptor causes increased release of mature neutrophils to the circulation (Eash *et al.*, 2009). Neutrophils enter the circulation in a resting state and can become primed by danger signals including bacterial products, cytokines and chemokines. Primed neutrophils are mobilized to the sites of infection or inflammation where they transmigrate into the tissues through interactions with the vascular endothelium. This process involves three steps:

Tethering and Rolling

Upregulation of endothelial cell adhesion molecules, such as selectins, initiates neutrophil tethering. This upregulation occurs through mobilization of P-selectins from Weibel–Palade bodies and by upregulation of *de novo* synthesis of E-selectins. Selectins are translocated to the apical membrane of the endothelial cell, where they transiently bind their respective ligands P-selectin glycoprotein (PSGL-1) and E-selectin ligand-1 (ESL-1), expressed by activated neutrophils. These interactions activate intracellular cascades that include Src family kinases Hck, Fgr, and Lyn that phosphorylate cytosolic proteins and trigger activation of syk (spleen tyrosine kinase). Activated syk triggers cytoskeletal rearrangement in the neutrophil leading to activation of kinases that result in integrin activation (Yago *et al.*, 2010; Ley *et al.*, 2007; Woodfin *et al.*, 2010; Barreiro and Sanchez-Madrid, 2009).

Firm Adhesion

Neutrophil rolling along the endothelium induces conformational changes in integrin adhesion of very late antigen-4 (VLA-4; $\alpha_4\beta_1$ -integrin, CD49d/CD29b), lymphocyte function-associated antigen-1 (LFA-1; $\alpha_1\beta_2$ -integrin, CD11a/CD18), and macrophage antigen-1 (MAC-1, $\alpha_M\beta_2$ -integrin, CD11b/CD18) that bind to adhesion molecules on the endothelial membrane such as intercellular adhesion molecule (ICAM)-1 and -2, vascular cell adhesion molecule-1 (VCAM-1), and mucosal vascular cell adhesion molecule-1 (MADCAM-1). LFA-1 is the key molecule that mediates the transition from rolling to adhesion (Phillipson *et al.*, 2006). These interactions trigger strong adhesion of the neutrophil to the endothelium, allowing for transmigration.

Transmigration

Neutrophils transmigrate into the affected tissues through the junctions between endothelial cells (paracellular transmigration) assisted by surface ligands ICAM-2, platelet endothelial cell adhesion molecule-1 (PECAM-1), and proteins of the junctional adhesion molecule (JAM) family (Woodfin *et al.*, 2009). Endothelial PECAM-1 interacts with GPI-CD177 (NB1-antigen) to facilitate transmigration (Sachs *et al.*, 2007). Transcellular transmigration accounts for approximately 20% of the transmigration mechanisms and occurs when neutrophils penetrate individual endothelial cells under conditions of high ICAM-1 expression and density (Yang *et al.*, 2006). SNARE proteins are essential in trafficking and fusion of intracellular organelles and exocytosis of granules to guide neutrophils across the endothelial cell body (Carman *et al.*, 2007). Once neutrophils migrate through the endothelium, they are exposed to a gradient of chemoattractants such as *N*-formylmethionyl-leucyl-phenylalanine (fMLP) and complement 5a (C5a). At the sites of infection, neutrophils, along with complement protein and immunoglobulin, recognize and bind opsonized bacteria, and execute the various antimicrobial mechanisms including phagocytosis, degranulation, and neutrophil extracellular trap (NET) formation. During these processes, released neutrophil molecules can also damage host tissue. Inflammation develops in response to pathogen-associated molecular patterns (PAMPs, such as lipopolysaccharide (LPS), flagellin, and nucleic acids) released into the tissue during infection, and also in response to damage-associated molecular pattern molecules (DAMPs, such as heat-shock proteins, high-mobility group box 1 (HMGB-1), ATP, and DNA) that are generated in response to sterile injury.

Neutrophil Defense Mechanisms

Neutrophils can eliminate microbes by various intracellular and extracellular mechanisms.

Phagocytosis

Neutrophils sense invaders through Toll-like receptors (TLRs) and other pattern-recognition receptors. Human neutrophils express almost all TLRs, except TLR3 (Janke *et al.*, 2009;

Hayashi *et al.*, 2003). Upon stimulation, TLRs trigger a cascade of intracellular events that induce inflammatory gene expression regulated by NF- κ B elements (Tamassia *et al.*, 2007). Microbes are internalized by neutrophils through phagocytosis. The phagosome fuses with lysosomes to form the phagolysosome, where the microbe is subsequently killed by generation of reactive oxygen species (ROS). ROS production is initiated by a nicotinamide adenine dinucleotide phosphate-(NADPH)-oxidase complex-dependent process called oxidative burst. During this event, oxygen is converted into superoxide and transformed into hydrogen peroxide by superoxide dismutases. Subsequently, MPO is released into the phagolysosome through fusion with azurophilic granules, where it catalyzes the conversion of hydrogen peroxide and chloride into hypochlorous acid (Klebanoff *et al.*, 2013).

Degranulation

During this process, neutrophil granules translocate to the phagosomal or plasma membrane, where they dock and fuse with the membrane to release their contents. The release of granular components is tightly regulated mechanism that leads to exocytosis. Granules' exocytosis requires increases in intracellular Ca^{2+} and ATP and GTP hydrolysis. Actin cytoskeleton reorganization is also required. Granule release from neutrophils depends on activation of intracellular signaling pathways, including β -arrestins, the Rho guanosine triphosphatase Rac2, soluble NSF attachment protein (SNAP) receptors, the *src* family of tyrosine kinases, and the tyrosine phosphatase MEG2 (Lacy, 2006). Molecules such as neutrophil elastase, cathepsin G, and lysozymes degrade virulence factors and the bacterial cell wall. Antibacterial proteins such as BPI, cathelicidin, and defensins not only have the capacity to kill microbes but also can damage the host's tissues.

NETs

During NET formation, large strands of decondensed DNA in complex with granular proteins are extruded from the cell (Brinkmann *et al.*, 2004). The precise molecular mechanisms leading to NET formation are not yet fully elucidated. Various stimuli can trigger NET formation, including receptor-mediated signals (e.g., through TLR engagement) or through calcium channel formation through ionophores. These signals initiate a cascade of events, where calcium is released from its reservoirs by activation of PKC. This leads to assembly of NADPH oxidase and ROS generation (Matute *et al.*, 2009). H_2O_2 triggers activation and dissociation of the complex named 'azurosome,' which is formed by neutrophil elastase, MPO, azurocidin, cathepsin G, eosinophil cationic protein, defensin-1, lysozyme, and lactoferrin, leading to translocation of neutrophil elastase and MPO to the nucleus (Metzler *et al.*, 2014). Once in the nucleus, elastase partially cleaves histones to promote chromatin decondensation (Papayannopoulos *et al.*, 2010; Metzler *et al.*, 2014). Peptidylarginine deaminase 4 (PAD4) is activated by PKC ζ and translocates into the nucleus where it citrullinates histones (Brinkmann *et al.*, 2004; Neeli and Radic, 2013). This phenomenon appears to be crucial for chromatin decondensation leading to NET

Figure 2 Cellular events during NETosis. NET formation is characterized by disintegration of the nuclear envelope followed by DNA decondensation. Neutrophils from a healthy volunteer were stimulated with LPS for 30 min. A resident nuclear membrane protein, lamin B was stained in red and vesicles were stained in green. Nuclear material was counterstained with Hoechst. Arrows indicate localization of lamin B before and after stimulation with LPS.

formation. The nuclear membrane disintegrates and decondensed DNA mixes with granules and cytosolic proteins (Figure 2). This complex of nuclear material and cytoplasmic and nuclear proteins is extruded to the extracellular space as NETs (Brinkmann *et al.*, 2004) that serve to trap and immobilize microbes and represent a lytic mechanism of neutrophil cell death. The presence of antimicrobial proteins (e.g., histones, defensins, elastase, proteinase 3, cathepsin G, lactoferrin, and MPO) in these structures supports their microbicidal role toward various pathogens, including bacteria, viruses, fungi, and parasites (Urban *et al.*, 2009; McCormick *et al.*, 2010). Neutrophils can also release mitochondrial DNA in NETs, without undergoing a cell death program (Yousefi *et al.*, 2009, 2008) in response to LPS and other stimuli. In addition, *Staphylococcus aureus* can trigger NET formation in a rapid, non-lytic, and oxidant-independent mechanism called vital NETosis (Pilszczek *et al.*, 2010). During this event, the plasma membrane remains intact. Vesicles containing DNA and proteins are pinched off from the nuclear membrane and fuse to the plasma membrane, releasing NETs. Vital NETosis has been also documented in response to TLR4-mediated platelets binding to neutrophils (Clark *et al.*, 2007).

Neutrophil Subsets

Given their short half-life, neutrophils have been difficult to study and characterize in detail. While considered a homogenous leukocyte subset for many years, emerging evidence suggests that these cells carry significant heterogeneity and plasticity with various degrees of phagocytic potential, protein synthesis, and oxidative metabolism. Indeed, various neutrophil subsets in response to physiological and pathological conditions have been described (Gallin, 1984; Beyrau *et al.*, 2012). It is still unclear if neutrophil subsets represent truly distinct lineages or develop from a single neutrophil precursor in response to the microenvironment. Up to this date, subsets

of neutrophils have been identified through expression of specific markers, gene expression, and functional aspects in healthy and pathological conditions. Some examples are mentioned below:

Olfactomedin 4-Expressing Neutrophils

Olfactomedin 4 (OLFM4) is a matrix glycoprotein expressed during the myelocyte and metamyelocyte stages of maturation, and levels of this protein decline as neutrophils mature (Clemmensen *et al.*, 2012). OLFM4 is expressed in approximately 25% of peripheral blood neutrophils and its presence is not regulated at the transcriptional level, suggesting microRNA (miRNA) regulation (Clemmensen *et al.*, 2012). OLFM4 is a granular protein that co-localizes with NGAL (Clemmensen *et al.*, 2012) and is externalized in NETs (Welin *et al.*, 2013). While the exact role of this neutrophil subset remains to be determined, OLFM4 may have immunoregulatory roles (Liu *et al.*, 2013).

CD177-Expressing Neutrophils

The glycoprotein CD177 (NB1) is a glycosyl-phosphatidylinositol-anchored receptor that is differentially expressed in circulating neutrophils (Stroncek, 2007; Hu *et al.*, 2009). Neutrophils that express CD177 demonstrate higher affinity to PECAM-1. CD177 associates with membrane PR3 promoting infiltration into tissues (Figure 3). CD177-positive neutrophils are increased in the autoimmune vasculitis granulomatosis with polyangiitis (Hu *et al.*, 2009). It also appears that these cells synthesize higher levels of IL-17. More information is required regarding their role in induction of tissue damage and vascular inflammation.

Low-Density Granulocytes

Low-density granulocytes (LDGs) are a distinct proinflammatory subset of neutrophils identified in the

Figure 3 Neutrophil heterogeneity. Emerging evidence supports the notion of heterogeneity among leukocytes. A subset of neutrophils expressing membrane-bound PR3 can be found in neutrophil preparations from healthy volunteers. PR3 is stained in green and DNA in blue. Scale bar 10 μm .

mononuclear cell fraction of patients with systemic lupus erythematosus (SLE) (Hacharth and Kajtacsy-Balla, 1986; Denny *et al.*, 2010) and other autoimmune conditions such as psoriasis (Lin *et al.*, 2011). LDGs synthesize higher levels of proinflammatory cytokines (Denny *et al.*, 2010) and are primed to form significantly higher numbers of NETs (Villanueva *et al.*, 2011). LDG-NETs contain higher concentrations of metalloproteinases, such as MMP-9 that trigger endothelial damage (Carmona-Rivera *et al.*, in press). Molecules externalized by LDG-NETs may serve as modified sources of autoantigens in SLE (Carmona-Rivera and Kaplan, 2013; Knight *et al.*, 2012).

Proangiogenic MMP-9 Delivering Neutrophils

Vascular endothelial growth factor (VEGF)-A facilitates the recruitment of a subset of neutrophils that express high levels of MMP-9 to a site of hypoxia. The $\text{CD11b}^+/\text{Gr-1}^+/\text{CXCR4}^+$ leukocyte subset has been reported to be involved in the revascularization of transplanted pancreatic islets. They are more primed and prone to respond to a hypoxic stimulus, expressing more CXCR4 and containing more MMP-9 with proangiogenic capabilities (Christofferson *et al.*, 2012).

T-Cell Regulatory Neutrophils

Recent evidence indicates that neutrophils can also have important regulatory roles in adaptive immune responses through effects on T and B lymphocyte proliferation, activation, and differentiation. A subset of human neutrophils that can suppress T cells response was identified in healthy

volunteers after intravenous LPS administration. Regulatory neutrophils are $\text{CD62L}^{\text{dim}}/\text{CD11c}^{\text{bright}}$, demonstrate hypersegmented nucleus and are capable of producing large quantities of H_2O_2 . Suppression of T cells requires formation of an immunological synapse through neutrophil $\alpha_{\text{M}}\beta_2$ -integrin (MAC-1) and large amounts of H_2O_2 (Pillay *et al.*, 2012). It remains to be better understood whether specific neutrophil subsets serve different roles in modulation of adaptive immunity.

Genetic Defects That Affect Neutrophil Numbers and/or Function

While genetic diseases that affect neutrophil numbers and function are rare, they provide additional understanding into the molecular mechanisms by which these cells are crucial in host defense. A few are mentioned below:

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) results from mutations in various neutrophil genes including neutrophil elastase (ELANE), HAX-1, and Gfi-1. Neutrophil formation is arrested at the promyelocytic stage, patients display very low neutrophil counts and develop life-threatening infections.

Leukocyte Adhesion Disorders

Leukocyte adhesion disorders (LAD) develop due to defects in neutrophil cell adhesion to the endothelium or the extracellular matrix. Mutations in genes encoding for specific integrins (such as LAD-I and LAD-II diseases) are characterized by severe infections due to defects in neutrophil recruitment.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is the most common of the genetic neutrophil function disorders. It is a heterogeneous group of hereditary diseases characterized by an inability of phagocytic cells to kill engulfed organisms due to defects in ROS generation through NADPH oxidase complex (Figure 4). This is due to defects in subunits of phagocyte NADPH oxidase (Kuhns *et al.*, 2010; Bianchi *et al.*, 2009). Patients suffer from recurrent, life-threatening infections, underlying the important role of ROS production in host defense.

Mutations in the Gene Encoding MPO

Mutations in the gene encoding MPO have been described in patients that suffer from recurrent *Candida* infections. One out of 3000 individuals may harbor mutations that affect MPO production, activity or trafficking (Winterbourn *et al.*, 2006).

Papillon-Lefèvre syndrome

Papillon-Lefèvre syndrome (PLS) is an autosomal recessive disorder caused by a deficiency in cathepsin C, an enzyme that

Figure 4 Genetic diseases that affect neutrophil function. Genetic alterations that affect neutrophil function can trigger life-threatening infections. Patients with mutation in subunits of the NADPH oxidase develop CGD. PLS is characterized by deficiency of proteinase activity present in azurophilic granules. Lack of secondary and tertiary granules is found in patients with mutation in the transcription factor C/EBP ϵ that develop neutrophil-SGD. Azu, azurophilic granules; Cath G, Cathepsin G; ELA, elastase; Gelat, gelatinase granules; MPO, myeloperoxidase; Spec, specific granules.

processes various serine proteases crucial in antimicrobial defense (Figure 4). The immunodeficiency that develops in these patients is mild and the mutation affects mostly mature neutrophils (De Haar *et al.*, 2006; Sorensen *et al.*, 2014).

Neutrophil-Specific Granule Deficiency

Neutrophil-specific granule deficiency (SGD) is a rare congenital disease where neutrophils display atypical bilobed nuclei and lack expression of secondary and tertiary granular proteins with multiple defects in antimicrobial strategies and severe bacterial infections (Figure 4). Mutations in the transcription factor C/EBP ϵ are the primary genetic defects (Gombart *et al.*, 2001).

Neutrophils in Systemic Autoimmune Diseases

While neutrophils are key players in the innate response to infections, they can also contribute to the development and

perpetuation of chronic inflammatory/autoimmune diseases. A few examples are mentioned below:

Vasculitis

Vasculitis is a group of diseases characterized by inflammation of the blood vessels. Small vessels vasculitis (SVV) is a subtype of this disease where patients synthesize anti-neutrophil cytoplasmic antibodies (ANCA) recognizing PR3 or MPO. Both activated neutrophils and ANCAs have been implicated in the development of vasculitis. MPO and PR3 are externalized during NET formation and autoantibodies against PR3 induce NETosis (Kessenbrock *et al.*, 2009). Dysregulated neutrophil cell death has been proposed to play a pathogenic role in SSV.

Rheumatoid Arthritis

Rheumatoid Arthritis (RA) is an autoimmune disease that results in destructive erosive inflammation of synovial joints (De Rycke *et al.*, 2004). Neutrophils are the most abundant

cells found in the synovial fluid of RA patients (Mohr *et al.*, 1981) and they form NETs more readily than control neutrophils (Khandpur *et al.*, 2013). Various citrullinated proteins released during NET formation are RA autoantigens (Khandpur *et al.*, 2013; Pratesi *et al.*, 2014). NETs induce a proinflammatory phenotype in fibroblast-like synoviocytes, which may lead to enhanced articular damage (Khandpur *et al.*, 2013).

SLE

SLE is a systemic autoimmune syndrome characterized by the development of autoantibodies to nuclear components, immune complex deposition, inflammation, and organ damage (Tsokos, 2011). Neutrophils may contribute to loss of tolerance and organ damage in SLE. Abnormalities in phagocytosis, activation, and NET formation have been described in SLE neutrophils (Brandt and Hedberg, 1969; Courtney *et al.*, 1999; Hashimoto *et al.*, 1982; Villanueva *et al.*, 2011; Carmona-Rivera *et al.*, in press). Dysregulated NET degradation through inhibition of DNase-I has also been described (Hakim *et al.*, 2010; Leffler *et al.*, 2012). NETs also promote synthesis of cytokines considered key in lupus pathogenesis and inhibition of NET formation decreases lupus phenotype in animal models (Villanueva *et al.*, 2011; Knight *et al.*, 2013).

Conclusion

Neutrophils are specialized, terminally differentiated cells that are endowed with crucial roles in host defense against microbes. Genetic or acquired deficiencies in neutrophil numbers or function can be life-threatening and lead to severe infections, while unchecked neutrophil responses or extended neutrophil half-life may lead to chronic inflammatory and autoimmune conditions. Neutrophils are more heterogeneous than originally described and many unanswered questions remain with regards to their specialization and plasticity and their interactions with other cells of the innate and adaptive immune system.

Specialized Subsets of Tissue-Resident Macrophages in Secondary Lymphoid Organs

A Chauveau and TI Arnon, University of Oxford, Oxford, UK

© 2016 Elsevier Inc. All rights reserved.

Macrophages are professional phagocytes that are able to efficiently engulf and digest extracellular particles, cell debris, and pathogens. They play critical roles in regulating host immunity and participate in many other biological processes from tissue repair mechanisms and clearance of apoptotic cells to regulation of metabolism and temperature control (Davies *et al.*, 2013; Murray and Wynn, 2011; Wynn *et al.*, 2013). Macrophages can be broadly divided into two classes: tissue-resident and infiltrating macrophages. Although resident macrophages have previously been thought to develop from circulating monocytes that originate from hematopoietic stem cells, recent findings challenged this dogma and revealed that in many cases resident macrophages are derived from yolk sac embryogenesis and have the capacity to self-renew during both steady state and following immunological challenges. It is likely that local signals derived from the tissue itself play key roles in promoting the specification of tissue macrophages, a notion supported by the strict correlation observed between macrophage's positioning and their phenotypic characteristics. However, the nature and identity of these signals are still largely unknown. Importantly, macrophages are not only heterogenous, but also adaptable and quickly modify their phenotype in response to environmental changes, a quality that endows them with the ability to adjust their function in a dynamic fashion (Martinez *et al.*, 2009).

The complex heterogeneity of mature tissue macrophages reflects a high degree of specialization and highlights the need to study these unique cells *in vivo*, in the context of their natural environments. In the past three decades, clodronate liposome treatment has been widely used *in vivo* to remove macrophages from lymphoid tissues and other sites (van Rooijen *et al.*, 1989). However, while this treatment is very effective in depleting phagocytes, it lacks selectivity and targets the majority of macrophage subsets as well as other cell lineages that are sensitive to the treatment (e.g., dendritic cells (DCs) and marginal zone (MZ) B cell). Attempts to generate mouse models with better specificity have been hampered by the considerable overlap in gene expression between closely related macrophage subsets and by the absence of single known selective markers that can distinguish between them. Recent efforts to generate comprehensive descriptions of gene expression profiles of tissue macrophages have greatly advanced the field and enhanced our ability to analyze macrophage biology with greater resolution (Gautier *et al.*, 2012). However, the development of mouse models based on these studies is lagging and the selective functions of many key macrophage populations remain poorly defined. Among those, macrophages that reside in secondary lymphoid organs have proved exceptionally challenging to study (Gautier *et al.*, 2012) partially due to their tendency to exchange surface markers with nearby lymphocytes (Gray *et al.*, 2012). In a recent careful analysis of fluorescence-activated cell sorting

(FACS) purified CD11b^{hi}CD169^{hi}F4/80⁺CD11c^{lo} from lymph nodes (LNs) of immunized mice, it was discovered that what were thought to be pure macrophage populations actually contained large numbers of contaminating T cells and natural killer cells that had acquired membrane protein containing macrophage-derived membrane blebs during the preparation procedure. This acquisition caused the lymphocytes to therefore appear by classical analysis as being macrophages. This caveat must therefore be considered when interpreting findings from past publications, but also highlights how critical it is that additional analysis such as microscopy or reverse transcription polymerase chain reaction (RT-PCR) are considered in all future work for ensuring that similar contamination issues are avoided. The development of better purification methods, and the generation of mouse models for selectively targeting major macrophage populations, will help to define the molecular basis of macrophage behavior and to identify their key functions in the context of complex biological settings.

Macrophage Subsets in the Spleen

The spleen is a major lymphoid organ that filters the blood. It provides critical protection from blood-borne pathogens and is important for the removal of antigens, foreign material, and damaged or aged red blood cells (Mebius and Kraal, 2005). To carry out its multiple functions, the spleen is organized in a modular fashion and is divided into several distinct compartments; the LN-like white pulp that is rich in lymphocytes, the surrounding red pulp where macrophages and transiting blood cells are abundant, and the MZ compartment that is located between them and is densely populated with macrophages and specialized subsets of lymphocytes (Mebius and Kraal, 2005). Most of the blood that enters the spleen is released into the MZ via sinuses that are located at the base of the compartment. These structures form a relatively impervious barrier on their follicular side, thereby restricting fluids and large molecules from entering the white pulp. However, on their outer side, the marginal sinuses are fenestrated, allowing free passage of blood contents into the MZ and red pulp. Venules that are scattered across the red pulp allow fluids and cells to egress the spleen and return into the blood circulation (Mebius and Kraal, 2005). Each one of these compartments contains typical macrophage subsets with distinct characteristics and functions (Figure 1). The best-described populations are found within the MZ and the red pulp and these are the focus of the next sections.

The Splenic MZ and Its Macrophages

The splenic MZ is an important transient region where newly arriving cells, antigens, and blood are filtered. Specialized cells

Figure 1 Illustration of spleen architecture and cellular composition of the marginal zone. The spleen can be divided into three main compartments: the red pulp (RP, grey), the white pulp (WP, white), and the marginal zone (MZ) that is located between them. The MZ and RP are separated by the marginal sinuses (ms). Breaks in the marginal sinus layer form the bridging channels (BC). Blood arriving via the central arteriole (CA) arrives to the marginal sinuses and passively flows through the MZ toward the red pulp and into venous sinuses. Metallophilic macrophages are located under the marginal sinuses, with some processes extending across the endothelial barrier (see also [Figure 2](#)). SIGN-R1/MARCO macrophages are located above the marginal sinuses and are found in close proximity with resident DCs and MZB cells. Circulating cells such as B cells enter the spleen with the blood and first arrive to the MZ. Some B cells may get caught in the blood flow and move toward the RP, while others transmigrate directly across the marginal sinuses to enter the follicles or move toward the bridging channels into white pulp. B cell migration between the MZ and the FO depends on G-protein coupled receptors (GPCR, black arrows) and is bi-directional, with some B cells using the MZ as an exit route to leave the FO. In the RP, the cell moves with the flow (shadowed arrows), enters a venous sinus and returns to circulation. MZB cells (green) are confined to the spleen and migrate back and forth between the MZ and follicular compartments in a GPC-dependent manner.

that reside in this compartment are involved in evaluating the nature of the arriving material and determining its fate. Within this region two major populations of macrophages have been identified; the metallophilic and the MZ macrophages ([Macauley et al., 2014](#)). Metallophilic macrophages are located at the inner ring of the MZ below the marginal sinuses ([Figure 2\(a\)](#)). They were named after their affinity for silver and are typically identified by high surface expression of the sialic-acid binding receptor CD169 (also known as Siglec-1) ([Macauley et al., 2014](#)). The second subset is found through the MZ compartment and is characterized by expression of the C-type lectin domain containing receptor SIGN-R1 and the scavenger receptor MARCO ([Figure 2\(b\)](#)). Although many published works use the term ‘MZ macrophages’ to describe these cells, in this article we will refer to them as ‘SIGN-R1/MARCO macrophages,’ whereas ‘MZ macrophages’ will be used as a collective name to describe both subsets. Importantly, the MZ is also home to MZB cells, a unique B cell subset that plays a central role in mounting rapid antibody responses against systemic pathogens ([Martin and Kearney, 2002](#)). In addition to recognizing and responding to cognate antigens, MZB cells express high levels of complement receptors (CD21 and CD35) and they are involved in the capture of opsonized antigens from the circulation and promoting their delivery into splenic follicles ([Arnon and Cyster, 2014](#)). A specialized subset of DCs also resides within the MZ and upon activation these cells migrate into the T zone and regulate T cell responses ([Mebius and Kraal, 2005](#)).

Notably, many circulating cells entering the spleen with the blood-flow pass through the MZ compartment and are likely to come into close contact with MZ macrophages. However, the nature and significance of such interactions remains largely unexplored.

Little is known about the specific factors that drive the differentiation of MZ macrophages in the spleen. Recently, an elegant report showed that the development of these cells depends on the expression of the liver X receptor alpha (LXR α) ([Noella et al., 2013](#)). This dependency was selective to macrophages that reside in the MZ and LXR α deficiency did not affect the development of macrophage subsets located in the red pulp or in other lymphoid tissues including in the LN, Peyer’s patches, liver, or intestine. Importantly, MZ macrophages could be efficiently reconstituted in LXR α deficient animals by adoptive transfer of wild type (WT) monocytes, thus demonstrating the capacity of circulating hematopoietic-derived myeloid cells to replenish them. Whether a local neonatal-derived precursor is responsible for homeostatic repopulation of MZ macrophages in WT animals, remains to be determined. Since oxysterols are known to bind LXR α and to inhibit inflammatory responses via negative regulation of IL-1 β expression ([Spann et al., 2012](#)), it is tempting to speculate that local splenic sterol derivatives may indirectly regulate systemic immunity by controlling the development of MZ macrophages.

Despite the fact that MZ macrophages have been the subject of intense investigation over the past three decades, there are

Figure 2 Macrophage populations in the splenic MZ. (a) Immunofluorescent staining of a frozen spleen section showing CD169+ metallophilic macrophages (green) and marginal sinus endothelial cells (MAdCAM-1+, red). On the right, a close up on 2 selected areas. In most cases, the macrophage body is located under the sinus, but occasionally cell processes are extended across the endothelial layer. (b) A frozen spleen section showing the heterogeneity of macrophage populations in the MZ. Sections were stained with anti-CD169 (green), anti-SIGN-R1 (blue) and anti-MARCO (red). WP, white pulp.

still limited tools to study these cells in detail. In addition to the clodronate liposome method mentioned above, several established genetic mouse models are commonly used to deplete MZ macrophages, including mice in which diphtheria toxin receptor (DTR) is restricted to CD11c⁺ or CD169⁺ cells. Whereas the later model provides higher level of selectivity for targeting macrophages (excluding DC subsets) (Miyake *et al.*, 2007), in both cases administration of DT leads to ablation of both metallophilic macrophages and SIGN-R1/MARCO macrophages. As a result, in many cases, it is not possible to determine which population of macrophage is responsible for specific functions. Additional more selective approaches are therefore needed to delineate the molecular mechanisms by which MZ macrophages regulate their unique niche-specific functions.

Metallophilic Macrophages

Metallophilic macrophages form a tight ring overlaying the marginal sinus lining that surrounds the B cell follicles (Figure 2(a)). They require macrophage colony-stimulating factor (M-CSF) for their development and are absent in *op/op* mice that lack M-CSF expression (Witmer-Pack *et al.*, 1993). Metallophilic-macrophages can be phenotypically distinguished from other macrophage subsets in the spleen by high surface expression of CD169. Because of their proximity to the follicles, they are able to closely associate with follicular B cells and these interactions provide a critical source of lymphotoxin (LT)- α 1 β 2, which is required for macrophage development and survival (Nolte *et al.*, 2004). In turn, metallophilic-

macrophages may provide B cells with important information and regulate their activation. Early studies have shown that humoral immunity against particulate bacterial antigens depends on macrophages in the MZ; when mice were treated with clodronate liposomes, antibody production was significantly reduced (Buiting *et al.*, 1996). These defects were partially normalized when metallophilic-macrophages were allowed to recover, which takes place before recovery of the SIGN-R1/MARCO macrophages, thus suggesting a role for these cells in the regulation of B cell responses (Buiting *et al.*, 1996). In addition to placing them close to the B cell follicle, the positioning of metallophilic-macrophages also provides them with access to blood antigens, therefore it seems likely that they will help to support humoral responses by promoting antigen delivery to B cells. However, unlike in LNs, where CD169⁺ subcapsular macrophages (SCMs) were shown to rally lymph antigens to naïve follicular B cells (discussed below), direct support for this model in the spleen is currently missing. A fundamental difference between the spleen and LNs is that in the latter, circulating B cells and lymph-borne antigens enter the tissue via different routes and their first encounter is in the follicles. In contrast, in the spleen B cells and systemic antigens enter through the same path and first reach the MZ, where at least two different subsets of macrophages reside. Thus, in this environment, antigen may be handled by different types of cells. This anatomical difference may reflect the spleen's unique role in protecting from blood-pathogens and the requirement for alternative strategies when facing systemically disseminated infections.

The contribution of MZ macrophages to B cell activation may go beyond their role in antigen presentation. In a recent report, clodronate liposome treated animals failed to develop germinal center B cell responses and this defect correlated with an inability of antigen specific B cells to migrate to the perimeter of splenic follicles (Nikbakht *et al.*, 2013). Localization of activated B cells at the follicle perimeter is part of the program that promotes their differentiation into germinal center B cells and this step brings them in close proximity to metallophilic-macrophages (Gatto and Brink, 2013). Migration of B cells to the follicles perimeter depends on activation of the G-protein coupled receptor GPR183 (Gatto and Brink, 2013; Pereira *et al.*, 2009) (also known as Epstein-Barr virus-induced gene, EBi2) by its ligand 7 α ,25-dihydroxycholesterol. In spleen and LN, the main source of 7 α ,25-dihydroxycholesterol is restricted to lymphoid stromal cells, which selectively express high levels of the enzymes required for its production (Arnon and Cyster, 2014; Gatto and Brink, 2013). Since clodronate liposome treatment causes global changes in the tissue's architecture, especially at the early time points after its administration, changes in stromal cell populations may have led to loss of EBi2 ligands and contributed to the observed impaired B cell migration. Importantly, the failure of animals depleted of MZ macrophages to form germinal centers in this study significantly exceeded the defects associated with EBi2 deficiency (Gatto and Brink, 2013; Pereira *et al.*, 2009), thus suggesting additional mechanisms are probably involved.

Although early data indicated that metallophilic-macrophages are dispensable for T cell activation (Aichele *et al.*, 2003), recent studies show that this may not always be the case and that metallophilic macrophages may be involved in transferring antigenic material to nearby DCs, thus facilitating cross-presentation to cytotoxic CD8⁺ T cells (Backer *et al.*, 2010). By immunizing mice with the antigen ovalbumin (OVA) conjugated to α CD169 antibody (α CD169-OVA), Backer *et al.* demonstrated that selective targeting of OVA to metallophilic macrophages leads to enhanced ability of splenocytes to prime cognate CD8⁺ T cells and trigger their cytotoxicity *in vivo*. This was mediated via cross-presentation of OVA peptides by DCs that efficiently captured the antigen from macrophages and presented it to CD8⁺ T cells. Importantly, OVA specific CD4⁺ T cells responses were not affected, suggesting a selective role for metallophilic-macrophages in regulating cytotoxic T cell activation. The way by which antigens are selectively transferred from metallophilic-macrophages to DCs is not clear, but it is possible that cellular migration is involved since treatment of mice with pertussis toxin (which blocks G-protein coupled receptor signaling and therefore inhibits cell movement) prevented this process (Backer *et al.*, 2010). Similar results were obtained when OVA was selectively targeted to metallophilic-macrophages using OVA-containing liposomal nanoparticles coated with high-affinity glycan ligands of CD169 (Chen *et al.*, 2012). Surprisingly, however, although immunization with α SIGN-R1-OVA did not elicit T cell activation, conjugation of OVA to MARCO antibody did. This is unexpected since MARCO is highly expressed on SIGN-R1⁺ macrophages. Thus, it is possible that the lower affinity of the α SIGN-R1-OVA conjugates for SIGN-R1, or temporal downregulation of the

receptor upon interaction with its antibody (as previously shown Kang *et al.* (2004)), may have reduced the stimulatory capacity of the complex. Alternatively, α MARCO-OVA immunization may have selectively targeted a specific subset of macrophages that expresses MARCO, but lacks SIGN-R1 (described below).

Importantly, in both pLNs and spleen, CD169⁺ macrophages are prone to infection by viruses as well as other pathogens. Infected CD169⁺ macrophages have been shown to provide an essential source of IFN- α that is critical for preventing viral dissemination and death (Honke *et al.*, 2012; Iannacone *et al.*, 2010). These findings proposed the possibility that local proliferation of pathogens within CD169⁺ macrophages may be advantageous to the host. In line with this hypothesis, a recent publication showed that CD169⁺ macrophages may in fact actively promote viral replication; in the spleen, infection of metallophilic-macrophages by vesicular stomatitis virus (VSV) was enhanced by expression of *Usp18*, a host protein that is preferentially expressed in these cells and inhibits phosphorylation of IFN- α/β receptor, thus increasing cellular permissiveness to infection (Honke *et al.*, 2012). In this study, infection of metallophilic-macrophages was not only critical for production of IFN- α , but also enhanced adaptive immunity. This suggest that restricted viral replication in macrophages may promote B and T cell activation by providing a local source of antigenic material. In support for this possibility, poor infection of metallophilic-macrophages in *Usp18*^{-/-} mice correlated with diminished antibody and CD4⁺ T cell responses (Honke *et al.*, 2012). It should be noted, however, that *Usp18* is also abundant in DCs (Honke *et al.*, 2013) and that reduced infection of DCs in *Usp18* knockout animals may have contributed to impaired activation of B and T cell responses in this study. Thus, selective removal of *Usp18* from specific subsets of myeloid cells may help to better understand the importance of this mechanism to host defense.

SIGN-R1/MARCO (MZ) Macrophages

SIGN-R1/MARCO macrophages are best identified by their positioning at the interface between the MZ and red pulp and by elevated expression of SIGN-R1 and MARCO receptors. In common with the metallophilic-macrophages, they require B cells and (LT)- α 1 β 2 for their development. However, unlike metallophilic-macrophages, these cells are excluded from direct contact with the follicles and are therefore restricted from accessing naïve follicular B cells. Instead, they interact with MZB cells that dwell in this compartment (Martin and Kearney, 2002). This unique population of cells migrates in the MZ from the underlying follicle in an integrin-dependent manner and is able to overcome the shear forces exerted by the blood flow in this region (Arnon and Cyster, 2014). Under steady state conditions, MZB cells move back and forth between the MZ and follicles in a perpetual movement, such that at any given time approximately half the cells reside within the MZ and half are in the follicles. This allows MZB cells to scan both compartments and to transfer information from one side to the other (Arnon and Cyster, 2014; Cyster and Schwab, 2012). Recently, we have established a method for visualizing cell movement within the MZ of live anesthetized mice using

2-photon microscopy. Using this approach, we visualized for the first time the highly motile nature of MZB cells and the tight interactions they form with SIGN-R1/MARCO macrophages (Arnon *et al.*, 2013); in many cases, MZB cells were observed to closely associate with immune complex-coated SIGN-R1/MARCO macrophages and appeared to scan their processes and cell bodies (Movie 1). Indeed, unlike metallophilic-macrophages, SIGN-R1/MARCO macrophages express high levels of complement receptors and this allows them to efficiently trap antibody-coated antigens within minutes after entering the blood stream. Expression of SIGN-R1 may also promote complement fixation and opsonization of antigens by inducing an unconventional pathway for C3 fixation, a process that was shown to be Ig-independent and to enhance complement-mediated innate resistance to pneumococci (Kang *et al.*, 2006). Immune complexes captured by SIGN-R1/MARCO macrophages are subsequently transferred to MZB cells, which carry them into the follicles and deposit them on follicular dendritic cells (FDCs) (Cyster and Schwab, 2012). Since antigen presentation by FDCs is important for germinal center B cell activation, this process may help to promote humoral immunity and the generation of high-affinity antibodies.

SIGN-R1/MARCO macrophages are not only important for providing MZB cells with antigenic material, but may also regulate their migration. Previous studies have shown that in the absence of SIGN-R1/MARCO macrophages, MZB cells were unable to localize to the MZ and their numbers were significantly reduced (Karlsson *et al.*, 2003; Noella *et al.*, 2013). Since development of MZB does not depend on access to the MZ (Cinamon *et al.*, 2004), it is likely that SIGN-R1/MARCO macrophages are not essential for their survival. Instead, they may be needed for retention (Karlsson *et al.*, 2003). The molecular basis of these observations has not been extensively explored, but one possibility is that gross changes in the architecture of the MZ due to loss of SIGN-R1/MARCO macrophages may compromise the development of local stromal cells and reduce expression of LFA-1 and VCAM-1, the integrin-ligands that regulate MZB cell adhesion (Arnon and Cyster, 2014; Cyster and Schwab, 2012). Alternatively, direct interactions with SIGN-R1/MARCO macrophages may help to restrict MZB cells movement and confine them to the MZ. Intravital imaging of MZB cell behavior in the absence of SIGN-R1/MARCO macrophages will help to differentiate between these possibilities.

While SIGN-R1/MARCO macrophages are typically referred to as a single population of cells, closer examination shows that they are in fact heterogeneous and that in addition to SIGNR-1⁺MARCO⁺ cells, the outer rim of the MZ also contains a subset of macrophages that lacks SIGNR-1 but expresses the MARCO receptor (Figure 2(b)). Notably, whereas SIGN-R1⁺MARCO⁺ macrophages depend on M-CSF for their development and require continuous interactions with MZB cells for survival (You *et al.*, 2009, 2011), SIGNR1[−]MARCO⁺ are independent of these factors, thus supporting the existence of two distinct populations of cells. Little is known about the functional specification of the SIGNR-1[−]MARCO⁺ macrophages and more studies are required to understand the importance of these cells to homeostatic mechanisms and to the regulation of immune responses.

Clearance of Apoptotic Cells by MZ Macrophages

The efficient removal of apoptotic cells is fundamental for the maintenance of healthy tissues and defects in apoptotic cell clearance are associated with immunological disorders and development of autoimmune diseases. Resident macrophages play central roles in this process and express a range of surface receptors that mediate the recognition and uptake of apoptotic cells in various tissues (Henson and Hume, 2006; Taylor *et al.*, 2005).

In the spleen, deletion of both MZ macrophage subsets impairs systemic tolerance toward apoptotic cells and accelerates the development and severity of autoimmune diseases (McGaha *et al.*, 2011; Miyake *et al.*, 2007; Wermeling *et al.*, 2009). The mechanisms by which MZ macrophages mediate these effects are only beginning to emerge, but may involve (1) direct clearance of apoptotic cells, (2) the transfer of apoptotic material to antigen presenting cells with suppressor capacity, and (3) the secretion of anti-inflammatory mediators. When MZ macrophages were removed, the spatial localization of apoptotic cells was altered such that dead cells were no longer confined to the MZ, but were accumulated in the T zone (McGaha *et al.*, 2011). Previous studies identified a unique subset of CD8 α ⁺ DCs that is able to capture dead cells in the splenic MZ, migrate into the T zone and inhibit T cell responses (Iyoda *et al.*, 2002; Qiu *et al.*, 2009). Thus, when MZ macrophages were depleted, apoptotic cells were no longer engulfed by CD8 α ⁺ DCs and instead were preferentially captured by CD8[−] DCs. This correlated with enhanced priming of cytotoxic T cells and a loss of tolerance (Miyake *et al.*, 2007). Systemic administration of apoptotic cells also triggered expression of the immunoregulatory enzyme Indoleamine 2,3 dioxygenase (IDO) in MZ macrophages (Ravishankar *et al.*, 2012). Inhibition of IDO using genetic or pharmacological approaches increased production of proinflammatory cytokines and enhanced effector T cell responses toward apoptotic cells (Ravishankar *et al.*, 2012). Although these studies were not able to specify the relative contribution of each macrophage population in the MZ to these processes, a recent report has shown that injection of apoptotic cells triggers expression of CCL22 specifically in metallophilic-macrophages (Ravishankar *et al.*, 2014). CCL22 mediated accumulation of FoxP3⁺ Tregs and blocking this pathway led to a strong proinflammatory response and breakdown of systemic tolerance (Ravishankar *et al.*, 2014). Importantly, however, since both metallophilic-macrophages and SIGN-R1/MARCO macrophages express a wide array of receptors that can recognize apoptotic and damaged cells, it is likely that both subsets are involved in maintaining peripheral tolerance in the spleen. In line with this notion, loss of expression of MARCO or scavenger receptor A (SR-A), which are abundant on SIGN-R1/MARCO macrophages, is sufficient to reduce the tolerance threshold and to increase anti-DNA antibody titers (Wermeling *et al.*, 2007).

Red Pulp Macrophages

The red pulp represents the majority of the spleen's volume. It lacks the well-defined organization of the white pulp and it is composed of a meshwork of sinuses and cords, which

Figure 3 Schematic description of cross-section of a red pulp cord with a venous sinus located in the middle. The cord is supported by a network of stromal cells (light brown). The sinus wall is composed of elongated endothelial cells (white) that are connected by stress fibers (orange dotted line). The fibers are contractible, allowing the opening of slits between the endothelial cells (pointed at by dashed arrow). Through these slits, red blood cells (red), and migrating cells (yellow) pass as they egress back to the systemic blood circulation. An example of a cell entering the sinus via a slit is illustrated (yellow arrow). Red pulp macrophages (pink) are located in the cord and some closely associate with the sinus wall. Aged or damaged red blood cells that become too stiff to squeeze between the slits are quickly phagocytosed by nearby macrophages. Following immunization, plasma cells (purple) migrate to the red pulp cord, where they may come to close contact with local macrophages.

together form an open blood system. Blood arrives to the red pulp after entering via the marginal sinuses and passing through the MZ. While most of the blood enters via this path, some terminal arteriole end within the red pulp and release their contents directly into the splenic cords. Venous sinuses that are scattered throughout the red pulp provide exit sites for blood and circulating cells that are returning back to circulation (Mebius and Kraal, 2005). The red pulp macrophages (RPMs) are located within the splenic cords, in close association with red blood cells and plasma cells (Figure 3). They develop prior to birth and are maintained throughout adulthood from a local progenitor, independently from circulating monocytes and bone marrow-derived hematopoietic cells (Hashimoto *et al.*, 2013; Yona *et al.*, 2013). Although under steady state only few RPMs actively divide, these cells are able to rapidly proliferate and expand in response to cell-targeted deletion or inflammation-induced ablation, thus demonstrating their capacity to self-renew under normal and pathological conditions (Hashimoto *et al.*, 2013; Yona *et al.*, 2013).

RPMs can be recognized in the spleen by the expression of $F4/80^+ CD206^+ CD11b^{lo}$ and $Vcam1^+$ (Taylor *et al.*, 2005). They play an important role in the regulation of erythrocytes turnover and iron recycling (Gordon and Taylor, 2005; Murray and Wynn, 2011; Taylor *et al.*, 2005). Damaged erythrocytes that are restricted from passage through the venous sinuses become phagocytosed and degraded by nearby macrophages. This process leads to the release of iron, which is important for the production of hemoglobin and other enzymes in new erythrocytes. In addition, RPMs express high levels of proteins that are involved in hemoglobin uptake, breakdown of heme and export of iron, thus providing an important reservoir of readily available iron that can be released to the plasma upon demand (Ganz, 2012). Since many extracellular pathogens require iron for their growth, restricting its availability by RPMs is thought to contribute to host defense mechanisms and attenuation of microbial proliferation. The mechanisms that control iron release from RPMs are only partially understood and more studies are needed to determine the signals involved and the importance of local versus systemic stimuli in regulating this process.

In line with their important role in iron metabolism, RPM development depends on the transcription factor Spi-c (Kohyama *et al.*, 2009), which is itself induced by one of the main products of hemoglobin degradation, heme (Haldar *et al.*, 2014). A similar mechanism was found to regulate the development of $F4/80^+ Vcam1^+$ macrophages in the bone marrow (Haldar *et al.*, 2014), thus demonstrating the importance of metabolites in driving the differentiation of tissue-resident macrophages. While all RPM depend on Spi-c for their development, only about half require M-CSF (Cecchini *et al.*, 1994), suggesting RPMs are likely composed of a heterogeneous population of cells. The phenotypic and functional differences between M-CSF dependent and independent RPM are not well understood. A recent study showed that in *op/op* mice a significant loss of RPM expressing low levels of complement receptor 3 (Mac-1) was observed, whereas $F4/80^+ Mac-1^{high}$ macrophages were still detected (Kurotaki *et al.*, 2011). *In vitro* assessment of $F4/80^+ Mac-1^{lo}$ cells in this study further suggested a possible role for this distinct macrophage population in suppression of $CD4^+$ T cell responses and induction of regulatory T cells (Kurotaki *et al.*, 2011). Further studies are required to better understand the heterogeneity among RPM populations and whether or not distinct subsets can be associated with specific anatomical niches within the red pulp.

Despite their potent phagocytic capacity and ability to mediate uptake of antigens, a dominant role for RPMs in protection against invading pathogens has been difficult to establish. For example, during exposure to malaria, infected erythrocytes and parasites are taken up by RPMs, leading to production of high amounts of chemokines and type I IFN (Kim *et al.*, 2012). However, these mechanisms were not essential for parasite clearance and *Spic*^{-/-} mice that selectively lack RPMs display a similar kinetics of malaria infection compared with WT animals (Kim *et al.*, 2012). Thus, while RPMs are able to respond and eliminate infected cells, their contribution to innate immunity may be largely redundant and is likely dominated by other more specialized macrophage subsets in the spleen. In support for this notion RPMs were found to critically contribute to the

clearance of *Streptococcus pneumonia* infection under conditions in which SIGN-R1⁺ macrophages were depleted (Kirby *et al.*, 2009).

LN Macrophages

LNs are distributed throughout the body and filter lymph from nearby tissues. Afferent lymphatic vessels enter the LN and bring tissue-derived antigens and cells (such as DCs) into the subcapsular sinus (SCS), a narrow space located below the LN capsule (Figure 4). The SCS surround the B cell follicles and the paracortical region where the T zone is located. The floor of the SCS is composed of lymphatic endothelial cells, which form a physical barrier that prevents free passage of large particles into the lymphoid tissue underneath. From the entry point at the SCS, the lymph flows into medullary and blind-ended cortical sinuses, before egressing the organ via the efferent lymphatic vessel. Circulating lymphocytes that enter the LNs from the blood do so by transmigration across the high endothelial venules (HEVs) in the paracortex. The B cells follicles are located underneath the SCS, at the cortical area, whereas T cells are positioned deeper in the paracortical region, which is centrally located between the medulla and cortex (Figure 4). The two best-described populations of resident macrophages in pLNs are found in close proximity to the subcapsular and medullary sinuses (Gray and Cyster, 2012). These macrophage subsets can be distinguished not

only based on their differential positioning but also by their phenotypic markers and functions.

SCMs

SCMs in LNs share many similarities with splenic metallophilic-macrophages; both cell types are located at the interface between the B cell follicles and sites of antigen entry, express high levels of CD169 and depend on M-CSF and B cell-derived LT α 1 β 2 signals for their development (Phan *et al.*, 2009). However, unlike metallophilic-macrophages, SCMs do not require LXR signaling and therefore develop normally in LXR deficient mice (Noella *et al.*, 2013). Although SCMs are efficiently replaced by donor bone marrow-derived cells in irradiated hosts (Gray *et al.*, 2012), it is currently not known whether these cells depend on circulating monocytes for their maintenance under 'normal' conditions or whether they instead renew locally under steady state. In human patients suffering from a RF8-null mutation that blocks monocyte and DC differentiation, LN macrophages develop normally, thus suggesting circulating monocytes may not be necessary for the survival of LN resident macrophages, at least in humans (Hambleton *et al.*, 2011).

Early histology studies have shown that shortly after subcutaneous injection of antigens, immune complexes captured by SCMs accumulate close to their contact area with follicular B cells. These observations raised the possibility that SCMs are important for the active transport of antigens across the

Figure 4 Illustration of lymph node compartments and localization of major macrophage populations. (a) The lymph node can be divided into three main regions; the cortex, the paracortex, and the medulla. Most circulating naive B and T cells arrive to the LN from the blood and enter by crossing the high endothelial venules (HEVs). Upon entry, B cells migrate to the follicles (FO) and T cells to the T-zone. In contrast to the path by which lymphocytes enter the LN, lymph arrives through the afferent lymphatic into the subcapsular sinuses that surround the follicles. From there, the lymph flows to the medullary sinuses, which are connected to the efferent vessel. LN macrophages are located at the entry and exit ports of the lymph; under the subcapsular sinuses (subcapsular macrophages, SCMs) and in the medulla (medullary macrophages). Some SCMs extend to the interfollicular regions (IFRs) that are located in the junctions between follicles and the T-zone. (b) A close up on the subcapsular region. The SCMs are shown in red, the follicles in green and the interfollicular regions are in grey. (c) A close up on a section from the medulla showing a medullary sinus (grey) surrounded by a cord. Macrophages can be found on both sides of the sinus wall. Based on a recent suggested nomenclature, we highlight the medullary macrophages that reside inside the sinuses (medullary sinus macrophages, light orange) and those that are in the cords (medullary cord macrophages, MCMs, orange). Plasma cells (purple), DCs (blue) as well as other myeloid cells can be found in the medullary cords.

SCS and for early stages in B cell activation. This notion has now been validated in a series of elegant studies using histology-based analysis (Pape *et al.*, 2007) and two-photon microscopy (Carrasco and Batista, 2007; Junt *et al.*, 2007; Phan *et al.*, 2007); in these studies, SCMs were shown to capture large antigen immune complexes from the afferent lymphatics and to transfer them into the underlying follicles. Follicular B cells were seen to migrate in close proximity to SCMs and were frequently found to scan their processes. These encounters allowed non-cognate B cells to capture immune complexes from SCMs and to transfer them at their uropod into the follicles in a CR2-dependent manner. Cognate B cells that came in contact with antigen-coated SCMs reduced their migration velocity with many forming long-lasting interactions, suggesting local activation was induced. In some cases, antigenic material was observed to move in a unidirectional fashion from the lymph exposed SCM cell body to the cell's processes that reach through the SCS into the follicle parenchyma. However, it remains unclear whether the antigen simply 'slides' along the macrophage body or is being internalized into endosomes and recycled back to the surface (Batista and Harwood, 2009; Cyster, 2010). Notably, SCMs have relatively limited phagocytic capacity and are able to retain intact antigens on the cell surface for long periods of time, thus supporting their role in antigen presentation to B cells (Batista and Harwood, 2009; Cyster, 2010). It is likely that acquisition of antigens is mediated by multiple receptors with partially overlapping specificities (Batista and Harwood, 2009; Cyster, 2010; Phan *et al.*, 2009). Interestingly, CD169 was recently shown to bind antigen-containing exosomes (Saunderson *et al.*, 2014), suggesting a previously unappreciated pathway for delivering antigenic material to LNs and splenic follicles.

Despite the important insights discussed above, the role of SCMs in promoting humoral immunity remains unclear, and when clodronate liposome treatment was used to remove all local macrophage subsets in pLNs, germinal center responses were not reduced and production of high-affinity antibodies was either not impaired (Gonzalez *et al.*, 2010; Iannacone *et al.*, 2010) or only marginally affected (Phan *et al.*, 2009). In some cases, antibody responses were even enhanced (Gonzalez *et al.*, 2010). Given the tissue damage associated with treatments that remove tissue macrophages, it is possible that reduced active transfer of antigens is compensated by excessive leakage of antigen across the damaged tissue (Cyster, 2010). Thus, additional approaches to selectively ablate or perturb macrophage functions are needed to clarify the full extent of their contribution to B cell activation in pLNs and other sites.

SCMs have also emerged as important regulators of cytotoxic T cells in pLNs, particularly during recall responses. Upon infection with lymphocytic choriomeningitis virus (LCMV) (Kastenmuller *et al.*, 2013), vaccine virus (VV) (Sung *et al.*, 2012), or the parasite *Toxoplasma gondii* (Chtanova *et al.*, 2009), central memory T cells rapidly accumulated at peripheral sites near the SCS, medulla, and interfollicular regions of the LN, where significant infection of macrophages was observed. Recruitment of memory CD8⁺ T cells to the infected sites required expression of CXCR3 ligands by a number of cells including CD169⁺ macrophages (Kastenmuller *et al.*, 2013; Sung *et al.*, 2012). Given that SCMs are thought to be

the main population of cells that becomes infected in the first few hours after infection, their contribution to early recruitment of memory T cells to infected sites may be critical. This mechanism may not only inhibit systemic dissemination of pathogens, but could also help to prevent local damage to the LN. It is not fully understood whether SCMs prime CD8⁺ T cells by directly presenting processed peptides via MHC class I molecules or indirectly, by transferring antigens to nearby DCs. Indeed, during inflammation, naive CD8⁺ T cells up-regulated expression of CCR5, which preferentially enhanced migration toward infected DCs. When CD11c⁺ DCs were removed, frequency and duration of contacts between T cells and SCMs were increased, but these interactions were only partially functional and resulted with suboptimal activation of T cells (Hickman *et al.*, 2011). Thus, more studies are needed to clarify the role of SCMs in direct priming of naive and memory T cells. Importantly, the nature of the antigen itself may also influence the stimulatory potential of SCMs. For example, in pLNs, visualization of interactions between SCMs and NKT cells using 2-photon microscopy demonstrated that SCMs are able to take up and directly present lipid antigens to NKT cells, thus establishing their capacity to function as antigen presenting cells (Barral *et al.*, 2010). In the spleen, CD169⁺ macrophages may function similarly (Kawasaki *et al.*, 2013), although in this study direct visualization of macrophages-NKT cell interactions was not described and the possibility that other indirect mechanisms are involved could not be excluded.

Medullary Macrophages

The medullary sinuses form a large irregular structure of winding tunnels, which are surrounded by medullary cords. These structures are filled with lymphatic fluids and are populated with a niche-specific macrophage subset known as the medullary macrophages (Gray and Cyster, 2012). The medullary sinus macrophages (MSMs) can be identified by their location inside the medullary sinuses and by their high expression of F4/80. In addition, many medullary macrophages also express CD169 (although at lower levels compared with SCMs), SIGN-R1, MARCO, and LYVE1 (Gray and Cyster, 2012). In contrast to SCMs, development of medullary macrophages is independent of M-CSF and they develop normally in op/op mice (Witmer-Pack *et al.*, 1993), confirming their identity as a distinct population of cells. Although like SCMs medullary macrophages are equipped with many surface receptors that can mediate the capture of bacterial, viral, and other pathogens, they contain a large number of lysosomes and are highly phagocytic (Taylor *et al.*, 2005; Phan *et al.*, 2009). As such, medullary macrophages are thought to play a more dominant role in degrading rather than presenting antigenic material to lymphocytes in LNs. This function may help to filter the lymph and prevent dissemination of pathogens to the systemic circulation. Notably, however, medullary macrophages are not impermeable and in some cases soluble proteins or other antigens that have escaped the SCMs may pass the medullary macrophages and reach the medullary cords (Gonzalez *et al.*, 2010), where nearby cells including local DCs may capture it and promote humoral immune responses. However, whether medullary

macrophages are actively involved in this process has not been established.

The medullary sinuses are connected to the efferent lymphatic vessels, where cells and fluids egress from the LN (Girard *et al.*, 2012). While these sinuses provide the path that leads lymphocytes out of the organ, in many cases, lymphocytes use the sinuses located in the cortical region to initiate egress. Live imaging and histology-based studies have provided a detailed analysis of this process and established a critical role for the sphingosine-1-phosphate receptor 1 (S1PR1) expressed on the surface of B and T cells in promoting cell migration across the lymphatic sinuses (Cyster and Schwab, 2012). Although the relative frequency of lymphocytes egressing directly via the medullary sinuses was not assessed and visualization of this process was not performed (Grigorova *et al.*, 2009), the observation that S1PR1-deficient T cells accumulate close to the medullary sinuses strongly suggest that this may be an important egress site where a similar mechanism of exit applies (Cyster and Schwab, 2012). Importantly, the main cellular source of the S1PR1-ligand, S1P, for egressing lymphocytes in pLNs is expressed by LYVE1⁺ lymphatic endothelial cells (Pham *et al.*, 2010). In mice in which the enzymes responsible for S1P production (sphingosine kinase 1 and 2) were selectively removed from LYVE1⁺ cells, T cell egress was significantly impaired. This defect was independent of LYVE1⁺ medullary macrophages and other hematopoietic cells since reconstitution with WT bone marrow did not restore normal egress (Pham *et al.*, 2010). Thus, medullary macrophages are not a major source for S1P for lymphocyte egress from pLNs. Interestingly, recent imaging studies revealed that the medullary sinuses are not only an exit site, but may also function as an entry path for T cells that arrive from the afferent lymphatic. Under steady state conditions, T cells preferentially used this path, whereas DCs migrated across the SCS (Girard *et al.*, 2012). Since most of the T cells that enter pLNs via the lymphatic system are primarily effector or memory cells, migration across the medullary region may provide an efficient way to rapidly scan activated medullary macrophages, where early pathogen detection occurs.

Despite being a significant distance from the follicles, medullary macrophages may play a role in supporting humoral immunity by promoting plasma cell survival. During immune responses, the medullary cords become packed with newly generated plasma cells and plasmablasts, many of which were reported as being in close proximity to myeloid cell lineages, including medullary macrophages (Mohr *et al.*, 2009). RT-PCR analysis showed that a few days after antigen immunization in alum, CD169⁺CD11b^{high}F4/80⁺ macrophages located at the centre of the medullary cords produced high amounts of IL-6 and APRIL. These factors are important for plasma cell survival and maturation, suggesting a potential role for medullary macrophages in providing trophic support to these cells (Mohr *et al.*, 2009). Live imaging studies have confirmed that plasma cells often form long-term interactions with LysM⁺ cells in the medulla, supporting a potential cross talk with local macrophages. Interestingly, in contrast to the proposed function of medullary macrophages in promoting plasma cell survival, in this study medullary macrophages were suggested to negatively regulate plasma cells leading to reduction in antibody

production and decreases in the number of plasma cells (Fooksman *et al.*, 2014). Notably, however, in this report adjuvant-free vaccination was applied, suggesting different modes of activation may differentially affect macrophages functions and interactions with plasma cells.

The level of heterogeneity between medullary macrophages is not fully understood and it is likely that these cells are composed of more than one subset. A recent review suggested a convenient nomenclature for classifying the cells based on their positioning differentiating between macrophages that reside inside the medullary sinus (MSMs) and those that are located in the medullary cords (medullary cord macrophages, MCMs) (Figure 2; Gray and Cyster, 2012). Given the tight link that exists between a macrophage's biology and their niche of residency, it is reasonable to speculate that these cell populations indeed represent different subsets and it would be important to resolve the unique characteristics and functions that define them.

Conclusions

Secondary lymphoid organs are highly organized structures in which antigenic material and rare lymphocytes come together in a temporally and spatially controlled manner to produce an efficient and well-balanced immune response. In addition to their important role in regulation of adaptive immunity, secondary lymphoid organs also function as biological filters, actively removing pathogens from lymph and blood. As such, these structures provide an important barrier that restricts pathogen dissemination and prevents spreading of disease. Within pLNs and spleen, macrophages occupy peripheral niches that are located at the interface between the circulatory fluids and the lymphoid tissue. This positioning brings them in direct contact with newly arriving antigenic material, where initial encounters with pathogens occur. Seminal early studies have identified this strategic positioning and provided profound insights that established the important roles of these cells in elimination of invading pathogens and in handling antigenic material. However, it is only in recent years that we begun to fully appreciate the highly specialized nature of these cells and their contributions to specific immunological functions. While current data strongly support a direct role for macrophages in facilitating antigen delivery to B cells, NKT cell and potentially CD8⁺ T cells, the mechanisms by which these processes are regulated and the long-term consequences of these interactions are poorly understood. These questions remain particularly unexplored in the spleen, where dynamic assessment of macrophage behavior using intravital imaging approaches has not been possible until recently, thus limiting analysis of interactions between splenic macrophages and immune cells. Uncovering mechanisms by which macrophages contribute to systemic versus local immune responses requires further investigation and better understanding of these processes may prove useful for future development of novel vaccine strategies.

More studies are also needed to delineate the basis for the complex heterogeneity of tissue macrophages and the cues that promote their specification *in vivo*. Revealing such factors will not only help to explain how the environment modifies the

immune system, but also to uncover the unique characteristics and requirements of the niche itself. Such knowledge may further help to identify specific transcriptional programs and may enable the development of new approaches to selectively manipulate distinct macrophage populations. Indeed, a major obstacle that continues to challenge the field and to prevent detailed mechanistic understanding of these cells is the absence of mouse models that selectively target individual macrophage types and the difficulties associated with their purification. Developing such tools and improving isolation protocols will undoubtedly enhance our ability to explore these cells *in vivo* and to obtain a comprehensive understanding of their biology and functions in the spleen, pLNs, and other sites.

CD4 T Cell Memory and Role of TNF Receptor Family

DR Withers and CL Marriott, University of Birmingham, Birmingham, UK

Overview

CD4 T cells play an array of critical roles within the immune system, aiding many other cell types through cytokine release, supporting the generation of high-affinity antibodies, whilst also directly targeting host cells infected with intracellular bacteria. This wide range of functions is facilitated by the generation of distinct subsets of effector CD4 T cells. Crucially, CD4 T cell responses generate memory cells, long-lasting populations able to better respond to antigen upon re-encounter, thus underpinning vaccination. Key to turning naïve CD4 T cells into effector and memory cells are interactions with antigen presenting cells (APCs) expressing peptide:MHCII complexes alongside a host of other surface receptors and ligands. A combination of signals through the T cell receptor (TCR) and other surface receptors, many of which are members of the tumor necrosis factor receptor super family (TNFRSF), shape this response and are crucial in ensuring optimal effector function and memory cell survival. Here, following a brief overview of CD4 T cell responses, we will discuss the role of different members of the TNFRSF specifically in the generation of CD4 T cell memory.

CD4 T Cell Responses

The initiation of CD4 T cells responses occurs within secondary lymphoid tissue, immune cell depots where naïve CD4 T cells patrol, searching for cognate peptides presented by APCs, typically dendritic cells (DCs; [Bajenoff et al., 2006](#)). Naïve CD4 T cell pools recognizing a specific peptide are very small, typically numbering 20–200 cells in the mouse ([Moon et al., 2007](#)). Therefore, extensive expansion of this population is required to generate a sufficient pool of effector cells that can perform the required functions. However, like an army too expensive to maintain, this effector population is rapidly reduced through apoptosis ([Kaeche et al., 2002](#)). This is accompanied by the emergence of a long-lived memory population with a half-life measuring several weeks ([Pepper et al., 2010](#)). This memory population can then provide protection for extended periods of time, poised to rapidly respond upon antigen reencounter. Thus, successful CD4 T cell responses progress through a series of stages, with rapid proliferation and expansion, then differentiation and survival, processes orchestrated by an array of receptor–ligand interactions; whereas naïve CD8 T cells require only brief stimulation for activation ([Kaeche and Ahmed, 2001](#)). CD4 T cells require more substantial stimulation, with intravital imaging revealing that prolonged contact between naïve CD4 T cells and antigen bearing DCs lasting several hours, was required to drive expansion ([Celli et al., 2007](#)). Activation of naïve CD4 T cells requires signals through the TCR ([Cantrell, 1996](#)) with factors governing the mechanics of the TCR:peptide/MHCII interaction such as TCR affinity key to the resulting signaling to the

T cell ([Corse et al., 2011](#)). It is clear that in addition to TCR:MHCII, further signals, termed costimulation, are required for productive CD4 T cell responses, with signaling through CD28 critical for driving the expansion of naïve CD4 T cells *in vivo* ([Shahinian et al., 1993](#); [Green et al., 1994](#)). Costimulatory signals through CD28 mediate production of IL-2 and other cytokines ([Fraser et al., 1992](#); [Thompson et al., 1989](#)), up-regulation of the IL-2 receptor ([Cerdan et al., 1995](#)), and proliferation ([Gimmi et al., 1991](#)). Due to the focus of this article, this very brief summary of TCR and CD28 signals, does not even scratch the surface of what is currently understood about these processes and their role in CD4 T cell responses.

The formation of memory populations as well as functional effector cells is clearly dependent upon signals received during the initial clonal expansion stage. Titration of the number of TCR transgenic T cells demonstrated that optimal memory cell formation required very low-precursor frequency, mirroring the size of endogenous naïve CD4 T cell pools ([Hataye et al., 2006](#)). Where high numbers of naïve TCR transgenic CD4 T cells were transferred, thus reducing the extent of DC interactions through competition, an effector cell pool with impaired function developed ([Blair and Lefrancois, 2007](#)). Whether memory cells form directly from naïve CD4 T cells, or reflect the persistence of a subset of the effector population is not completely resolved. Several studies have shown that interferon- γ (IFN γ)-producing effector cells differentiated into memory populations as efficiently as IFN γ [−] cells ([Lohning et al., 2008](#); [Harrington et al., 2008](#); [Pepper et al., 2010](#)), demonstrating that effector cells can give rise to memory cells. Amongst CD4 memory cells, distinct populations of T effector memory (Tem) and T central memory (Tcm) have been described with the latter able to recirculate through secondary lymphoid tissue through differential expression of CD62L and chemokine receptors ([Pepper et al., 2011](#); [Sallusto et al., 1999, 2004](#)). Once formed, murine memory CD4 T cells require the cytokines IL-7 and IL-15 for survival ([Seddon et al., 2003](#); [Kondrack et al., 2003](#); [Purton et al., 2007](#)). Interestingly, memory CD4 T cell survival is independent of MHCII, indicating that further signaling through the TCR is not required ([Purton et al., 2007](#)).

Members of the TNFRSF and CD4 T Cells

The TNFRSF contains 19 ligands and 30 receptors ([Croft, 2009](#)), whose interactions underpin a diverse range of roles in the immune system from lymph node development to T cell survival. Against the backdrop of TCR:peptide MHCII interactions and CD28 family costimulation outlined above, several members of the TNFRSF have been shown to contribute to the success of CD4 T cell responses, in general, supporting the proliferation, cytokine production, and survival of activated CD4 T cells, events downstream of naïve CD4 T cell proliferation driven by TCR and CD28 signals ([Watts, 2005](#);

Croft, 2009). The intracellular regions of these TNFRs associate with TNFR-associated factors (TRAFs) which feed into both the canonical and noncanonical nuclear factor- κ B (NF- κ B) signaling pathways (So and Croft, 2013). These receptors also convey signals through the phosphoinositide-3-kinase (PI3K) and Akt pathway, key to T cell activation, to which other costimulatory signals (such as CD28) contribute (So and Croft, 2013). Therefore, signals through TNFRs may contribute to multiple programs within the T cell and these processes remain incompletely understood. Of the TNFRs discussed in this article, all signal through TRAF2, thought to be key in supporting T cell responses (So and Croft, 2013; Watts, 2005). Since many TNFRs signal through the same TRAFs, there may be redundancy in their requirements, however, the defects observed in mice specifically lacking individual TNFRs argue that different members of this family cannot completely substitute for each other, likely due to the involvement of additional signaling components. The context within which antigen is encountered as well as infection type and chronicity will also clearly contribute to TNFR signal requirements, influencing the duration and pattern of expression. Simplistically, some TNFRs such as 41BB (TNFRSF9) and TNFR2 (TNFRSF1B) appear more important for CD8 T responses, rather than those of CD4 T cells (Kim and Teh, 2001, 2004; Dawicki *et al.*, 2004). Cross talk between the activated T cell and DC, through $LT\alpha_1\beta_2$ (rapidly expressed after activation) and $LT\beta$ R (TNFRSF3), ensures full DC maturation and thus optimal support for CD4 T cell priming (Summers-DeLuca *et al.*, 2007). Whilst induced on activated CD4 T cells, many TNFRs are constitutively expressed on regulatory T cells, further complicating our understanding of their roles in CD4 T cell responses (Croft, 2009). Here, we will focus on CD27 (TNFRSF7), Death receptor 3 (DR3, TNFRSF25), Herpesvirus entry mediator (HVEM, TNFRSF14), OX40 (TNFRSF4), and CD30 (TNFRSF8) all of which directly contribute to expanding and sustaining CD4 T cells and the resulting memory population (Figure 1).

In assessing memory CD4 T cell responses, the generation of this population, its subsequent survival and then its

requirements to respond to antigen reencounter are all important phases where different signals appear to be required. As discussed below these stages are, to varying degrees, controlled by signals through these TNFRSF members.

CD27

CD27 (which binds CD70) is expressed on most (including naïve) CD4 T cells, with anti-CD27 antibodies enhancing T cell expansion *in vitro* (Gravestine *et al.*, 1995). CD27 can bind to TRAFs 2 and 5 signaling through the NF- κ B pathway (So and Croft, 2013). CD27-deficient mice show reduced primary responses to influenza virus and impaired formation of memory CD4 T cells (Hendriks *et al.*, 2000), whilst constitutive expression of CD70 drives effector CD4 T cell expansion and overproduction of IFN γ (Arens *et al.*, 2001). Therefore, CD27 signals mediate survival in responding cells governing the size of the effector cell pool and thus development of memory CD4 T cells.

DR3

DR3 is another member induced following T cell activation, that upon binding TL1a signals through the NF- κ B pathway via TRAF2 (Migone *et al.*, 2002; So and Croft, 2013). Whilst DR3^{-/-} mice showed no impairments in CD4 T cell differentiation, effector T cell accumulation and cytokine production was significantly reduced in several experimental disease models consistent with a role sustaining effector CD4 T cells and thus influencing formation of the memory CD4 T cell pool (Meylan *et al.*, 2008).

HVEM

In contrast to many of the other TNFRSF members discussed here, HVEM is expressed by naïve, effector and memory cells, CD4 T cells and can bind to either LIGHT (homologous to lymphotoxins, exhibits inducible expression, and competes

Figure 1 Expression of TNFRSF members at different stages of a CD4 T cell response. Members of the TNFRSF are differentially expressed by CD4 T cells during an immune response. Bold font identifies molecules where there is clear experimental evidence pointing to a role specifically at this stage in the response.

with HSV glycoprotein D for HVEM, a receptor expressed by T lymphocytes) or BTLA (B and T lymphocyte attenuator) (Soroosh *et al.*, 2011). HVEM signals through the NK- κ B pathway, binding TRAFs 1, 2, 3, and 5 (Marsters *et al.*, 1997) impacting on CD4 T cell proliferation and cytokine production (Scheu *et al.*, 2002). Signals through HVEM appear particularly important for memory CD4 T cell survival in recall responses (Soroosh *et al.*, 2011). HVEM^{-/-} TCR transgenic T cells proliferated normally following secondary challenge and initially produced normal amounts of cytokine. However, this expanded memory population was not sustained in the absence of HVEM, which correlated with a decline in levels of phosphorylated Akt in HVEM^{-/-} T cells (Soroosh *et al.*, 2011). These data indicate that memory CD4 T cells may require certain members of the TNFRSF at very specific stages in a response, with HVEM seemingly key to maintaining memory cells after challenge.

OX40 and CD30

Of all the TNFRSF members implicated in CD4 T cell responses, OX40 and CD30 appear to be most important for survival and effector function. OX40 (which binds OX40L) was first recognized for its induced expression on rat (Mallett *et al.*, 1990), then mouse (Calderhead *et al.*, 1993) CD4 T cells, where *in vitro* and *in vivo* expression occurs within approximately 24 h of activation, peaks after a further 24–48 h, and is then rapidly lost (Gramaglia *et al.*, 1998, 2000; Rogers *et al.*, 2001; Marriott *et al.*, 2014). However, this expression pattern is clearly dependent upon the context in which antigen is encountered, with the brief expression described typical of acute infections (Marriott *et al.*, 2014), whilst in chronic infections expression on antigen-specific CD4 T cells can be maintained for many days (Boettler *et al.*, 2012). Expression of OX40 is downstream of CD28 signals (Walker *et al.*, 1999) and not required for initial naïve cell proliferation (Rogers *et al.*, 2001). Rather, OX40 signals via canonical NF- κ B and the PI3K/protein kinase B pathways to maintain clonal expansion, through sustained proliferation (mediated by molecules such as survivin and aurora B) and survival through promoting expression of the anti-apoptotic proteins Bcl-XL and Bcl-2 (Song *et al.*, 2008, 2005; Rogers *et al.*, 2001). Mice deficient in OX40 or its ligand show impaired CD4 T cell expansion and function but normal B cell responses (Chen *et al.*, 1999; Pippig *et al.*, 1999; Kopf *et al.*, 1999; Rogers *et al.*, 2001). OX40 signals are also important in the context of autoimmune responses, for example, blockade of OX40L reduced the severity of collagen-induced arthritis (Yoshioka *et al.*, 2000), whilst allergic inflammation in a murine asthma model was dependent upon OX40 (Jember *et al.*, 2001).

Like OX40, CD30 is induced upon activated CD4 T cells by CD28 signals or IL-4 and whilst less studied than OX40, also enhanced CD4 T cell responses (Toennies *et al.*, 2004; Gilfillan *et al.*, 1998). Both OX40 and CD30 bind TRAFs 1, 2, 3, and 5, although it is less clear whether CD30 signals through the PI3K-Akt pathway (So and Croft, 2013). Consistent with redundancy in the requirements of CD4 T cells for OX40 and CD30 signals, mice deficient in both these receptors (CD30^{-/-}OX40^{-/-}) were significantly more impaired in their CD4 T cell responses than either OX40^{-/-} or CD30^{-/-} mice

(Gaspal *et al.*, 2008, 2005). As described for OX40^{-/-} mice this was not due to impaired proliferation early in the response, rather due to very poor survival *in vivo* (Gaspal *et al.*, 2005). Furthermore, whilst mild defects in the germinal centers of CD30^{-/-} mice were observed, these structures were not maintained in CD30^{-/-}OX40^{-/-} mice (Gaspal *et al.*, 2005). As mentioned above, the formation of a robust memory CD4 T cell population is dependent upon the success of the clonal expansion stage. Memory CD4 T cells residing in the small intestine lamina propria were absent in CD30^{-/-}OX40^{-/-} mice, but only partially reduced in CD30^{-/-} or OX40^{-/-} mice, indicating both CD30 and OX40 signals contribute to the generation of CD4 T cell memory (Withers *et al.*, 2009). Perhaps most strikingly, CD30^{-/-}OX40^{-/-} mice crossed onto the FoxP3^{-/-} background were protected from the lethal autoimmunity that results from the absence of Tregs (Gaspal *et al.*, 2011). It is worth noting that scurfy mice (loss of function mutation in FoxP3) crossed with CD28^{-/-} mice were only partially protected and succumb to autoimmunity after several months (Singh *et al.*, 2007), consistent with CD4 T cell priming in the absence of CD28 under conditions of chronic stimulation (Kawai *et al.*, 1996). The lack of autoimmunity in FoxP3^{-/-}CD30^{-/-}OX40^{-/-} mice really demonstrates the absolute requirement for CD30 and OX40 signals in sustaining a functional CD4 effector pool. Mice deficient in FoxP3 and either OX40 or CD30 survived longer than FoxP3^{-/-} mice, yet still developed autoimmunity. Combined these data demonstrate that signals through both CD30 and OX40 are critical for the generation of effector CD4 T cells and the subsequent formation of a memory CD4 population.

Given the requirements for OX40 reported in many mouse models of infection, autoimmunity, and inflammation, it appears that there is no simple dichotomy in Th1 or Th2 responses and their requirement for signals through OX40 and CD30 (Watts, 2005). Early studies using TCR transgenic T cells reported impaired survival without further dissection of effector types (Kim *et al.*, 2003; Rogers *et al.*, 2001). More recently, reduced numbers of Tem, but not Tcm, have been reported in OX40^{-/-} and CD30^{-/-}OX40^{-/-} mice, assessing both total CD4 and antigen-specific populations (Soroosh *et al.*, 2007; Marriott *et al.*, 2014). *In vivo* administration of agonistic anti-OX40 antibodies drive substantial expansion of Tem (Boettler *et al.*, 2013; Marriott *et al.*, 2014), but not other subsets, likely through sustaining Blimp-1 expression (Boettler *et al.*, 2013). Given that expression of CD30 and OX40 is rapidly lost on effector CD4 T cells, such requirements would appear to reflect interactions with APCs early in the response. Therefore, can all the defects seen in the absence of CD30 and OX40 be attributed to a lack of signals during clonal expansion? It is not clear that once formed, memory cells require OX40 signals for survival as well as cytokines such as IL-7 (Kondrack *et al.*, 2003; Seddon *et al.*, 2003). Interestingly, *in vitro* culture with IL-7 induces OX40 expression on memory CD4 T cells suggesting that induction of OX40 expression on memory CD4 T cells may be antigen independent (Gaspal *et al.*, 2005). This would provide a further mechanism whereby recirculating memory cells might be maintained by interactions with OX40L⁺ cells within secondary lymphoid tissue (Withers *et al.*, 2011). However, arguing against this notion, *ex vivo* antigen-specific memory CD4 T cells generated

following acute infection with an attenuated *Listeria monocytogenes* strain, lacked OX40 expression (Marriott *et al.*, 2014).

Whilst the data described here refers exclusively to murine CD4 T cells, a human patient deficient in OX40 was recently described as having impaired Tem populations with poor IFN γ responses to recall antigens (such as Bacillus Calmette–Guérin (BCG), tetanus toxoid, Epstein–Barr virus (EBV), cytomegalovirus (CMV)) despite earlier exposure (Byun *et al.*, 2013). Therefore, this first human patient provides strong evidence that the OX40 requirements of murine CD4 T cells may be true of human CD4 T cells. That said, much more work on CD4 T cell expression and dependency on members of the TNFRSF is required to facilitate the clinical targeting of these molecules.

The rapid expansion of memory T cells upon antigenic challenge is one of their defining characteristics. Traditionally it has been thought that costimulatory molecules are dispensable for memory cell activation, however, some studies indicate that OX40 signals are required for optimal recall responses. Expression of OX40 is very rapidly upregulated on memory CD4 T cells upon challenge (Marriott *et al.*, 2014). Accumulation of OX40⁺ memory cells was found to be impaired in response to airway challenge in sensitized animals when OX40–OX40L signals were blocked (Salek-Ardakani *et al.*, 2003). OX40 interactions were also found to be required for optimal secondary responses to influenza and using TCR transgenic OTII cells an even greater effect was found with a complete lack of recall response in OX40L^{−/−} mice, despite no significant effect on priming (Dawicki *et al.*, 2004). It is unknown whether CD30 also contributes to memory cell expansion or survival upon challenge, although secondary antibody responses were abrogated in CD30^{−/−} OX40^{−/−} mice (Gaspal *et al.*, 2005). Therefore, OX40 and likely CD30 are key molecules in generation functional effector CD4 T cells, through effects on both expansion and survival during clonal expansion. These signals are critical in establishing a functional effector CD4 T cell pool during a primary response and the subsequent memory cell population. Upon challenge, memory CD4 T cells still require OX40 signals for optimal expansion.

Who Provides the Ligands?

Whilst the consequences of binding the different TNFRSF members is becoming clear, it is still uncertain which cells are the key source for many of the TNFSF ligands. The ligands CD30L, OX40L, CD70, LIGHT, and TL1a each have a diverse pattern of expression, inducible on many cell types (Croft, 2009). Given that their receptors are often temporally expressed on activated CD4 T cells, professional APCs are likely to be the key source of these signals, sustaining CD4 T cells during clonal expansion. Activated CD4 and CD8 T cells can also be induced to express these ligands suggesting T cell–T cell interactions are also important (Croft, 2009). For example, the impaired memory cell survival observed in HVEM^{−/−} T cells, was recapitulated when T cells were deficient in LIGHT, indicating that T cell–T cell interactions supported this process (Soroosh *et al.*, 2011). It seems likely that the key cellular source of these ligands will be dependent upon the nature of the infection or condition, with integration of other stimuli orchestrating ligand expression. Under conditions of

inflammation, non-hematopoietic cells such as endothelium and airway smooth muscle can express ligands such as TL1a and OX40L (Imura *et al.*, 1996; Burgess *et al.*, 2004; Croft, 2009) which may contribute to sustaining activated CD4 T cells at these sites. We have been particularly interested in lymphoid tissue inducer (LTi)-like cells, a ROR γ t-dependent cell that has seen revived attention due to the emergence of the innate lymphoid cell family (Spits *et al.*, 2013). LTi-like cells constitutively express OX40L and CD30L and support memory CD4 T cell survival *in vitro* and *in vivo* (Kim *et al.*, 2003, 2006; Withers *et al.*, 2012). In the embryo, LTi cells function to orchestrate lymph node development through interaction with stromal cells and at this developmental stage lack OX40L and CD30L expression. After birth, these cells acquire further functions including antigen presentation and processing (Hepworth *et al.*, 2013) as well as OX40L and CD30L expression (Kim *et al.*, 2006). Whilst a rare population, these cells are located clustered in lymph nodes and other secondary lymphoid tissue at sites of memory cell recirculation suggesting that these cells could interact and sustain memory CD4 T cells via OX40L (Withers *et al.*, 2011). However, direct evidence that *in vivo* LTi-like expression of OX40L and CD30L mediates memory cell survival is currently lacking. Furthermore, these cells express LIGHT (Kim *et al.*, 2006), which may also contribute to memory cell survival via HVEM. With the current widespread availability and use of conditional knockout mice, the precise details of who interacts with whom and when can be carefully elucidated, facilitating the clinical targeting of these pathways.

Concluding Remarks

Several TNFRSF members contribute to optimal CD4 T cell responses through expanding and sustaining effector CD4 T cells and the resulting memory pool. Whilst many of these molecules contribute to the same signaling pathways, it is becoming apparent that certain molecules are key at different stages of the CD4 T cell response. There are now clear data that combined signals through OX40 and CD30 are required for a functional effector cell pool, particularly in an autoimmune setting, suggesting these are excellent therapeutic targets for controlling CD4 T cell responses.

Introduction

According to current statistics and future projections of the National Institute on Aging (NIA, 2011), people aged 65 and older represent around 8% of the global population and will raise to around 16% by 2050. At present, this demographic shift toward an aged population is more evident in developed, industrialized societies, but is becoming an increasingly important phenomenon in developing societies as better health care, nutrition, and technological innovations become widely available.

Aging is an extremely complicated process, affecting all organs and tissues at different rates in different individuals. However, a closer examination of many of the major age-associated diseases has revealed that the process of aging is essentially the loss of tissue homeostasis, or a decline in the ability of stem cells to maintain or regenerate tissues over time due to a loss of stem cell function (Lopez-Otin *et al.*, 2013). In this article, we review some of the general aspects of stem cell biology associated with the aging and loss of function of most stem cell types; we then discuss these changes in relation to specific types of stem cells such as muscle stem cells (satellite cells), hematopoietic stem cells (HSCs), and mesenchymal stem cells (MSCs). In addition, we discuss potential ways by which aging may be countered by novel pharmacological and therapeutic interventions and the potential impact of this greater understanding of stem cell biology on the emerging field of stem cell therapies.

Determinants of Stem Cell Aging

Adult or somatic stem cells (SCs) represent a small population of long-lived progenitor cells that reside in an undifferentiated

state within most fully differentiated adult tissues. SCs are fundamental for maintaining tissue homeostasis and for mediating growth and regeneration after damage or disease. The major mechanisms by which SCs are regulated are similar between different SC types and are often altered or defective during aging. Therefore, understanding these mechanisms is essential to determine how aging affects SC behavior and to provide points of control by which SC behavior may be modified in genetic animal models or by pharmacological intervention.

Adult SCs are maintained in a specialized microenvironment called the 'niche,' which has often been proved difficult to study in detail, but whose particular features are gradually being unraveled. One of the principal roles of the niche is to provide a local environment rich in growth factors, trophic factors, and cytokines, which act in concert to sustain and support specific SC properties such as a quiescence, metabolic status, or the ability to activate and respond quickly to signals of tissue damage and repair (Jasper and Kennedy, 2012; Jones and Rando, 2011). Regulation of the niche, the quiescent state, and the transition from quiescence to activation are fundamental processes that may change during disease and aging.

Once activated, SCs proliferate and then differentiate as they contribute to the replacement or maintenance of the damaged tissue or organ. There is a great deal of heterogeneity in the proliferative behavior and potential of different types of adult SCs, reflecting the different regenerative requirements of each tissue. Skeletal muscle is generally a stable post-mitotic tissue, and satellite cells proliferate only when required, such as after injury, whereas the SCs of the hematopoietic system or the intestine, both high-turnover tissues, contain SCs with a high proliferative capacity to ensure homeostasis. The rate of

Figure 1 Stem cell regenerative potential declines with aging.

SC proliferation needs to be tightly regulated to ensure that adequate numbers of progeny are produced; too many cells could disrupt tissue architecture, whereas too few could fail to restore homeostasis (Liu and Rando, 2011; Li and Clevers, 2010). Importantly, stem cell proliferation is often impaired during aging, with examples of loss of proliferative potential and other examples of over-proliferative behavior.

In terms of differentiation, adult SCs have a defined potency depending on the tissue, being restricted to the generation of particular lineages to ensure ordered programs of tissue/organ repair. However, these programs often become aberrant with age, leading to defective regeneration. Alterations include both skewed lineages (as observed in HSCs) and adoption of alternative lineages (as observed in satellite cells) (see below).

A fundamental aspect of SC behavior is also the ability to self-renew and thus to replenish the SC population. This process is essential for ensuring preservation of the regenerative capacity of the tissue over time; loss of self-renewal will lead to SC depletion and therefore failure of homeostasis and repair (Simons and Clevers, 2011). Aging-associated defects in self-renewal have been reported in the majority of tissues, including the brain, the hematopoietic system, and the skeletal muscle.

Thus, the effects of aging on SC function can manifest at any of these levels of control and function, from dysregulation of the niche, to activation, proliferation, differentiation, and self-renewal (Figure 1). In the following sections we discuss the specific cell-intrinsic and -extrinsic alterations that may cause these shifts in function, and we focus on some particular cell models in which they have been studied.

Genetic Alterations

DNA damage and repair

Maintaining the integrity of DNA throughout the lifetime of an organism is fundamental to survival and the avoidance of disease, particularly cancer. Many mechanisms exist for the protection and proofreading of DNA in all species during cell division, but also during less active cellular states where metabolic by-products such as reactive oxygen species (ROS), exogenous chemical agents, and other environmental factors are still potentially dangerous. Indeed, endogenous DNA damage has been shown to accumulate with age in HSCs, with functional consequences (Rossi *et al.*, 2007). Specific mouse genetic models have been instrumental in demonstrating the DNA protection and repair mechanisms deregulated in aging HSCs, such as homologous recombination mediated by the FANCD1/BRCA2 gene, which is mutated in models of Fanconi anemia (Navarro *et al.*, 2006). In this sense, progeroid or

premature aging syndromes such as Werner syndrome or Bloom syndrome, among others, have principally been linked to mutations in genes involved in DNA repair (Burke and Stewart, 2014).

One mechanism that SCs use to minimize the potentially negative consequences of cell division and/or exposure to ROS is to adopt a nondividing and dormant state called quiescence. The exact cell cycle state that quiescent cells adopt is still controversial (see below), but it is accepted that, to repair DNA breaks, quiescent cells utilize the error-prone nonhomologous end-joining (NHEJ) pathway (Mohrin *et al.*, 2010). NHEJ function in the absence of cell division is based on a repair mechanism that does not require homologous strand guidance, but instead ligates the ends of double strand breaks together, utilizing very short homologous DNA sequences called microhomologies that are produced during the break. This is, however, an error-prone mechanism that may lead to insertional mutations and ultimately genomic instability (Mohrin *et al.*, 2010). Importantly, reduction of NHEJ pathway activity has been reported during aging (Vyjayanti and Rao, 2006), while genetic alterations in key components of the NHEJ pathway have been linked with aging phenotypes (Rossi *et al.*, 2007).

Telomere shortening

Telomeres are specialized and repetitive ribonucleotide protein structures located at the ends of chromosomes; they protect the chromosomal DNA from degradation and unwanted fusion with other chromosomes. It is widely accepted that, in somatic cells, each round of cell division reduces telomere length such that telomeres function as molecular clocks and therefore have an essential link to aging. Conversely, some cell types, particularly SCs and cancer cells, retain or restore mechanisms to preserve telomere length and thus obtain extended longevity or even immortality. However, age-associated telomere shortening in several adult SC compartments has been reported and can influence function (Flores *et al.*, 2008). As each round of replication reduces telomere length, a telomere will eventually reach a critical threshold, at which point a state of replicative senescence is induced, the so-called Hayflick limit (Hayflick and Moorhead, 1961). Cellular senescence is characterized by G1 cell cycle arrest, which is mediated by induction of p16^{INK4a}, retinoblastoma (RB), and p53 proteins and a state of persistent DNA damage often associated with apoptosis (D'Adda Di Fagagna *et al.*, 2003). Clearly, an SC that has achieved a state of cellular senescence is unable to repopulate or repair a damaged tissue, and this inverse relationship between telomere length and SC function has been demonstrated in adult tissues from several animal models of telomerase deficiency and mice with short telomeres even in the presence of telomerase (Flores and Blasco, 2010).

Epigenetic Alterations

Age-dependent alterations in the epigenome, such as alternating patterns of DNA methylation and posttranslational modifications of histones, can also affect chromatin structure and therefore the access of transcription factors and accessory

proteins to genes, which consequently alter tissue homeostasis and regeneration.

Histone acetyltransferases (HATs) and deacetylases (HDACs) have been extensively studied in relation to aging (Berger, 2007). Sirt2 HDAC has been shown to enhance the replicative lifespan of several invertebrate models (Longo and Kennedy, 2006). The unique requirement of Sirt2 and its orthologs for NAD and its varying effects on longevity in different nutritional states creates a firm link between metabolism and aging. Regarding histone methyltransferases, the lifespan of *Caenorhabditis elegans* has been shown to be modified by histone methylation, including trimethylation of histone H3 at lysine 4 (H3K4me3), a mark associated with active chromatin, which is mediated by the trithorax (TrxG) complex of proteins. In particular, knockdown of several TrxG members was shown to extend *C. elegans*' lifespan (Greer *et al.*, 2010). The polycomb repressive complex 2 (PRC2) complex of proteins trimethylates histone H3 on lysine 27 (H3K27me3), a mark which transcriptionally silences chromatin. Global epigenetic profiling of young muscle SCs showed that in quiescence their chromatin is maintained in a transcriptionally permissive state, with a large number of genes marked with H3K4me3 at the transcription start sites (TSS), and a few marked with H3K27me3, which would allow quiescent satellite cells to be primed for activation and differentiation (Liu *et al.*, 2013). During aging, the epigenetic scenario changes, with a global increase of H3K27me3 across the genome, coinciding with an increase in dsDNA breaks and a reduction in histone biosynthesis (Liu *et al.*, 2013).

Genome-wide studies have also suggested that there is a global age-associated loss of DNA methylation in human, rat, and mouse tissues (Issa, 2014). In particular, hypermethylation of the promoters at specific loci, as well as a progressive loss of 5-methylcytosine content, particularly within DNA repeated sequences, was shown to correlate with aging (Issa, 2003). Similarly, high-throughput analysis of the methylation status of CpGs islands has also shown age-dependent hypermethylation of PRC2 target gene promoters across multiple cell types, including blood, ovarian cancer, cervix, and MSCs (Teschendorff *et al.*, 2010). These results have been confirmed in aging SCs of the human colon, which identified a global increase of DNA methylation in conjunction with the accumulation of methylation errors (Yatabe *et al.*, 2001). More recently, a hypothesis linking changes in epigenetics and DNA methylation in HSCs has been proposed to explain the bias in differentiation toward the myeloid lineage that is seen with age (Bocker *et al.*, 2011). Therefore, understanding the epigenetic mechanisms may reveal why there are gradual shifts in SC proliferative and differentiation potential with age.

Cellular Consequences of Genetic and Epigenetic Changes

Two of the potential consequences of age-related genetic and epigenetic changes in SCs that could significantly affect the regenerative potential of SCs and tissue homeostasis are senescence and apoptosis. Senescent cells are known to accumulate in many aged tissues. The most studied markers include senescence-associated beta-galactosidase; senescence-associated heterochromatin foci, which are domains of facultative heterochromatin seen in senescent cells; phosphorylation of

the histone H2A variant H2AX (γ H2AX), which form foci and are well-established markers of double strand breaks and chromatin modifications linked to DNA damage and repair; and finally, senescent cells often express the cyclin-dependent kinase inhibitor and tumor suppressor protein p16^{INK4a}, which is a well-described biomarker of aging and senescence (Sharpless and DePinho, 2007). The importance of p16^{INK4a} in the age-associated decline in NSC and HSC proliferation has been shown by several groups (see below). Finally, direct evidence for increased apoptosis in different stem cell compartments is still lacking (Pollack and Leeuwenburgh, 2001), though apoptosis of SCs has been described in association with telomere dysfunction (Sperka *et al.*, 2012).

Aging in Adult Stem Cells

Muscle Stem Cells

Loss of skeletal muscle regenerative potential during aging

Adult skeletal muscle is a stable, post-mitotic tissue whose role is primarily contraction, which generates force and movement, as well as being an important contributor to body metabolism and heat production. The capacity of skeletal muscle to regenerate is provided by a unique population of muscle stem cells, the satellite cells, which reside beneath the basal lamina of muscle fibers and normally reside in a quiescent state until activated by damage or growth signals (Yin *et al.*, 2013). Skeletal muscle aging is associated with a loss of muscle mass and function known as sarcopenia (Zwetsloot *et al.*, 2013), and it is associated with a progressive decline in muscle stem cell function (Hikida, 2011). Here we briefly discuss the key findings of recent years related to satellite cell aging.

Extrinsic factors associated with satellite cell aging

Extrinsic factors known to influence satellite cell behavior include the structure and function of the niche and extrinsic signals which may be derived from systemic sources or from local inflammation during tissue remodeling. Regarding the niche, a key recent study found that niche-derived FGF2 in aged muscle fibers caused a down-regulation of Sprouty1 in satellite cells, which correlated with the increased tendency of aged satellite cells to exit quiescence or to undergo self-renewal (Chakkalakal *et al.*, 2012). These authors had previously shown that Sprouty1, a receptor tyrosine kinase signaling inhibitor, could negatively regulate FGF signaling and was necessary for self-renewal and return to quiescence in satellite cell subsets during regeneration (Abou-Khalil and Brack, 2010; Shea *et al.*, 2010).

Other studies have shown that the levels of TGF β , but not the related protein myostatin, are increased in aged muscle (Carlson *et al.*, 2008). Increased TGF β signaling enhances Smad transcription factor activation in aged satellite cells, which antagonizes Notch-dependent transcription of the cyclin-dependent kinase inhibitors p15^{INK4b}, p21^{CIP1}, and p27^{KIP1}. Therefore, enhanced Smad3 activation in old satellite cells inhibits satellite cell proliferation and limits the regenerative capacity of aged muscle. Consistent with this, inhibition of Notch induces these cyclin-dependent kinase inhibitors, whereas forced inhibition of Smad3 signaling could

partially rescue the muscle regeneration defect in old mice, suggesting that dysregulation of the endogenous Notch/Smad3 balance in aged satellite cells alters regenerative capacity (Carlson *et al.*, 2008).

Elevated levels of Wnt have also been found in the circulation of aged individuals, and neutralization of Wnt signaling in aged mice was able to restore efficient muscle repair (Brack *et al.*, 2007). More recent studies have shown that effective regeneration of muscle requires a switch from high Notch activation to high Wnt activation, which promotes satellite cell differentiation, in part by inactivating glycogen synthase kinase 3 beta (GSK3 β), which is normally maintained in the active state by Notch (Brack *et al.*, 2008). These results may also reflect the proposed role of the Notch pathway in satellite cell homeostasis, as loss of Notch signaling may help satellite cells bypass self-renewal in favor of differentiation, thereby reducing the capacity of satellite cell numbers to be replenished (Mourikis *et al.*, 2011; Bjornson *et al.*, 2011). Similarly, aged satellite cells showed delayed cell cycle entry and exit (Zwetsloot *et al.*, 2013) and also fail to appropriately up-regulate the Notch ligand Delta1. Consequently age-associated regenerative defects can be reproduced in young satellite cells by inhibition of Notch signaling, whereas muscle regeneration in aged mice can be partially restored by delivery of active Notch (Conboy *et al.*, 2003, 2005; Wagers and Conboy, 2005).

Some of the most compelling evidence for the impact of age-associated changes in the stem cell niche has come from elegant experiments that have experimentally restored 'youthful' characteristics to the stem cell environment and thus improved regeneration in aged rodents. Heterochronic tissue transplants (Harrison, 1983; Carlson and Faulkner, 1983) and heterochronic parabiosis (Brack *et al.*, 2007; Villeda *et al.*, 2011; Conboy *et al.*, 2005), in which young donor material (cells, blood, tissue extracts, myofibers, etc.) are transplanted into old hosts, or vice versa, have been shown to rejuvenate muscle stem cells. In the earliest studies, the grafting of minced muscle extracts from old mice onto muscle beds of young mice, or heterotransplantation of old muscles into young mice, improved regeneration to comparable levels in young animals (Gutmann and Carlson, 1976; Carlson and Faulkner, 1989; Roberts *et al.*, 1997). Further studies using heterochronic parabiosis also support the idea that the young environment is able to rejuvenate the regenerative potential of older satellite cells. In these technically challenging experiments, the circulatory system of young and old animals is joined, and after muscle injury regeneration of old muscle was as efficient as in young muscle, while the opposite was also true, with young muscle showing a diminished regenerative capacity (Conboy *et al.*, 2005; Brack and Rando, 2007; Villeda *et al.*, 2011). In agreement with other studies described above, restoration of Notch signaling was shown to be an important mechanism both *in vivo* after heterochronic parabiosis, and *in vitro* after treatment of aged satellite cells with young serum to restore replicative capacity (Carlson and Conboy, 2007; Conboy *et al.*, 2005; Wagers and Conboy, 2005). Treatment of young satellite cells with serum from old mice has the opposite effect, as would be expected (Carlson and Conboy, 2007). Recent publications searching for the circulating protein responsible for the heterochronic parabiosis-induced effects have isolated growth differentiation factor 11 (GDF11) (Sinha *et al.*, 2014)

and oxytocin (Elabd *et al.*, 2014) as possible rejuvenating factors. Overall, these results clearly suggest that there is both an absence of pro-myogenic factors and a presence of inhibitory factors in old mice that have important consequences on satellite cell, and perhaps SC, function.

These results have proved controversial, since experiments with heterotransplanted whole muscle grafts between old donors and young mice showed a delayed but proficient regeneration when compared with controls (Shavlakadze *et al.*, 2010; Smythe *et al.*, 2008). It was proposed that the slow early regeneration rate is due to delayed inflammatory and angiogenic responses in aged mice. However, it is still not clear whether dysregulated and persistent inflammation plays a direct or indirect role in age-associated satellite cell dysfunction.

Intrinsic modifications in aged satellite cells

Cell-intrinsic aging effects have been linked to loss of satellite cell function with age; these include oxidative damage, DNA damage and genome instability, and alterations in mitochondrial function (Garcia-Prat *et al.*, 2013). In the absence of Ku80, a component of the NHEJ pathway as described above, skeletal muscle develops an accelerated aging phenotype that was hypothesized to be due to telomere shortening and accumulated DNA damage (Didier *et al.*, 2012). Excessive demands on repair over a lifetime or in chronic disease may cause successive rounds of satellite cell activation and proliferation and give rise to telomere erosion, reducing the proliferative potential of aged satellite cells (Garcia-Prat *et al.*, 2013; Jung and Brack, 2014).

High-throughput gene expression profiling of young and old human satellite cells has highlighted differences in the transcriptional program that could alter function, including dysregulation of myogenic differentiation-specific genes, increased expression of atrophy-related forkhead (FoxO)-regulated genes, and altered expression of genes related to protein folding (Bortoli *et al.*, 2003; Pietrangelo *et al.*, 2009). Consistent with this are studies that show an impaired differentiation capacity in aged satellite cells, including the ability to fuse into myotubes or to form a reserve population *in vitro* (Collins *et al.*, 2007; Charge *et al.*, 2002). Reduced formation of myogenic colonies and a decreased ability to activate and proliferate are other defective processes identified by others (Shadrach and Wagers, 2011; Conboy *et al.*, 2003; Shefer *et al.*, 2006; Day *et al.*, 2010; Baj *et al.*, 2005). Moreover, it is now widely accepted that aged satellite cells show a tendency to adopt fibroblastic and adipogenic fates (Brack *et al.*, 2007), which may explain the increased levels of fat and fibrotic tissue in aged muscle. These changes may arise from a global epigenetic switch from H3K4me3 at the TSS to H3K27me3, coinciding with an increase in dsDNA breaks and a reduction in histone biosynthesis (Liu *et al.*, 2013).

Supporting the relevance of age-associated intrinsic alterations in satellite cell regenerative functions, a recent study showed that in geriatric animals (28 months of age or older), satellite cells are in an irreversible pre-senescent state that affects their intrinsic regenerative and self-renewal ability (Sousa-Victor *et al.*, 2014). Maintenance of quiescence in adult life appears to depend in part on the active repression of senescent pathways, and in particular on repression of the p16^{INK4a} locus. Silencing of p16^{INK4a} is sufficient to rejuvenate

geriatric satellite cells, by restoring their activation potential and self-renewal capacity *in vivo* and *in vitro* and reestablishing regeneration efficiency (Sousa-Victor *et al.*, 2014). Finally, recent papers have also proposed rejuvenation strategies that act, independently of the environment, to reverse satellite cell-intrinsic changes that occur during the aging process (Cosgrove *et al.*, 2014; Bernet *et al.*, 2014; Tierney *et al.*, 2014; Price *et al.*, 2014). The authors show that p38 α / β MAPK and JAK/STAT activities are elevated in adult and aged satellite cells and that inhibition of any of these pathways is sufficient to restore satellite cell activity.

MSCs

MSCs, also called multipotent stromal cells or mesenchymal stromal cells, can be isolated from a variety of tissues, including bone marrow, adipose tissue, dental pulp, amniotic fluid, Wharton's jelly, and umbilical cord blood. Morphologically, MSCs are frequently described as being fibroblast-like, with a spindle shape and a large round nucleus; they have the capacity to differentiate *in vitro* into a vast range of cell types including mesenchymal cells such as adipogenic, osteogenic, and chondrogenic cells; they can also be induced to transdifferentiate into epithelial cells, such as gastrointestinal tract epithelial cells, alveolar epithelial cells, kidney cells, and also such endodermal cells as hepatocytes (Lee *et al.*, 2004). Functionally, MSCs have been widely described as having important immunomodulatory properties, including the ability to modulate T-cell and B-cell functions by affecting processes such as cell activation, proliferation, and chemotaxis mediated by direct cell-to-cell contact and/or the secretion of soluble factors (Yu and Kang, 2013; Raveh-Amit *et al.*, 2013).

Age-related changes in MSCs

The production of large numbers of purified MSCs for therapeutic purposes has created concern about potential age-associated effects due to donor age and/or extensive proliferation during manufacture. Indeed, there is sufficient evidence of age-related changes in MSCs, and therefore one of the most pressing research questions to emerge has been to identify the molecular basis for these changes. Not surprisingly, epigenetic alterations in MSCs have emerged as a possible cause of shifts in function, whereas several studies have also identified the importance of senescence programs. Culture of MSCs was shown to greatly affect epigenetic and gene expression patterns, increasing osteogenic genes and decreasing the 'stemness' of the cells. Epigenetic dysregulations include alterations in histone H3 acetylation, as well as changes in the methylation patterns of CpG islands in the promoter and the region of exon 1 in many genes (Li *et al.*, 2011).

Previous data showed that administration of HDAC inhibitors induced p21^{CIP1} expression and arrested MSCs in the G2/M phase of the cell cycle, and ultimately also induced p16^{INK4A} expression and cellular senescence, in a mechanism implicating the up-regulation of jumonji domain-containing 3 (JMJD3), which demethylates H3K27Me3 at the CDKN2 locus, thereby increasing p16^{INK4A} expression and down-regulation of several PcGs genes (Jung *et al.*, 2010). Overall, this study suggested that p16^{INK4A} is repressed in young MSCs

because of PcG-induced H3K27Me3, but that HDAC inhibition mimics aging by allowing p16^{INK4A} expression and cellular senescence. Importantly, this phenotype could be reversed in the presence of HAT inhibitors, which suggests a simple way by which premature senescence could be overcome, thereby enhancing the potential of MSCs. Consistent with these results, small interfering RNAs targeting p16^{INK4A} in senescent MSCs reduced the number of senescent cells and restored the ability to proliferate (Shibata *et al.*, 2007). Moreover, up-regulated p16^{INK4A} expression and down-regulated CDK4, CDK6, and RB, in conjunction with loss of proliferation, differentiation potential, and immunogenic properties, were identified in MSCs from patients with systemic lupus erythematosus (SLE), a systemic autoimmune disease in which the immune system attacks the heart, joints, skin, lungs, blood vessels, liver, kidneys, and nervous system. These effects were counteracted by knockdown of p16^{INK4A} expression, revealing a potential therapeutic strategy for treating these patients (Gu *et al.*, 2012).

It is worth noting that MSCs possess several important characteristics that make them potentially ideal as cellular therapies for a range of diseases, including those with significant morbidity and mortality in the elderly. These properties include immunomodulatory functions, an immune privileged status, easy isolation from a range of tissues, and ability to cross the blood-brain barrier, and are therefore of great interest in targeting many diseases, including cardiovascular disease and neurodegenerative disorders (Yu and Kang, 2013; Raveh-Amit *et al.*, 2013).

HSCs

Stem cell biology and the effects of aging on SCs have been most widely studied in the hematopoietic compartment. HSCs are a heterogeneous population of cells that reside in the red bone marrow (BM); they undergo self-renewal as well as proliferation and differentiation to repopulate the different blood lineages, giving rise to myeloid cells (monocytes and macrophages, neutrophils, basophils, eosinophils, erythrocytes, megakaryocytes/platelets, dendritic cells) and lymphoid cells (T-cells, B-cells, and NK-cells) (Orkin and Zon, 2008). One of the most surprising aspects of HSCs and the BM niche is that the number of HSCs increases with age, which is in contrast to most other SC populations (Beerman *et al.*, 2013, 2010). The reasons for this are not completely understood and are probably multifactorial. Clear functional differences between old and young HSCs have been shown. For example, transplantation of young and old HSCs together into lethally irradiated young recipients shows a greatly reduced potential for grafting by older cells (Morrison *et al.*, 1996). In this sense, it is also well described that aged HSCs have a preference for differentiation toward the myeloid lineages, as already stated above, which leads to an overall decrease in the regenerative potential of HSCs and the overall capacity of the immune system (Geiger *et al.*, 2013; Beerman *et al.*, 2010). What is not clear is the interplay over time between cell-intrinsic and cell-extrinsic factors in facilitating these changes. These factors are discussed briefly below.

One of the hallmarks of aging in HSCs is a differentiation potential that favors the myeloid lineage at the expense of the

lymphoid and erythroid lineages (Geiger *et al.*, 2013). Many mechanisms have already been proposed for this observation, but among the alternative hypotheses are that HSCs do not lose their differentiation potential *per se*, but that preference for the myeloid lineage merely reflects changes in composition of the HSC pool, presumably due to defects in self-renewal of some HSC clonal subtypes during aging, though other mechanisms have been postulated, such as accumulation of DNA damage (Beerman *et al.*, 2010).

Several groups have shown a clear role for the loss of genome integrity and DNA damage as a cause of altered HSC function with age, similar to the models of progeroid syndromes described above. Mutations or deletions in various DNA repair components have been shown to modify HSC behavior and function. Hypomorphic mutations in DNA ligase IV (LIG4), a component of the NHEJ, are associated with multiple defects in lymphocyte development, function, survival, and proliferation (Nijnik *et al.*, 2007). Knockout of another NHEJ protein, Ku80, induce severe defects in T- and B-lymphocyte development and profound deficiencies in V(D)J recombination, the process by which B-cell and T-cell receptor diversity is generated. However, mutation to other DNA repair processes not related to V(D)J recombination are also involved in loss of HSC potential, suggesting that other mechanisms are also at play. For example, deletion of exon 27 of the BRCA2/FANCD1 gene, which is involved in homologous recombination, results in marked defects in proliferation and in the self-renewing ability of HSCs in a mouse model of Fanconi anemia (Navarro *et al.*, 2006). Collectively, these data suggest that an increased mutation rate, as in aging, may give rise to proliferative advantages, failure of adequate differentiation, and ultimately malignant transformation.

There are also links between DNA repair and the accumulation of damage due to ROS. The ataxia telangiectasia mutated (ATM) protein is a serine/threonine protein kinase that is activated by DNA double strand breaks, where it phosphorylates several key proteins, including tumor suppressors, to initiate activation of the DNA damage checkpoint, cell cycle arrest, DNA repair, or apoptosis. Activation of p38 MAPK in response to increasing levels of ROS normally limits the lifespan of HSCs *in vivo*, but in *Atm*^{-/-} knockout mice, elevation of ROS levels induces HSC-specific phosphorylation of p38 MAPK accompanied by a defect in the maintenance of HSC quiescence, defects in repopulating capacity, and ultimately depletion of the HSC pool (Ito *et al.*, 2006). These defects in repopulation potential can be overcome by suitable treatment with antioxidants, demonstrating a link between DNA repair and ROS with age. Deletion of autophagy-related protein 7 (Atg7) (Mortensen *et al.*, 2011) in adult mice also increases ROS levels and consequently causes HSC depletion, linking ROS and autophagy HSC homeostasis and aging. Interestingly, a recent report demonstrated that autophagy is essential to protect HSCs from metabolic stress (i.e., induced by starvation or cytokines) in a mechanism controlled by FOXO3A and maintained in old HSCs (Warr *et al.*, 2013). Interestingly, recent new data on HSC suggest that accumulation of DNA damage with age is related to a reduction of the DNA repair mechanisms when HSCs are in quiescence. When stimulated to enter the cell cycle, only fetal and young HSCs are able to up-regulate the DNA response and repair pathways to resolve that accumulated damage (Beerman *et al.*, 2014).

In addition to their roles in regulating quiescence as described above for satellite cells, FoxO transcription factors have been shown to be important regulators of oxidative stress throughout the lifetime of an organism, and by association also affect changes in HSC function with aging. FoxO3a conditional ablation in mice was shown to impair HSC self-renewal, reducing the frequency of HSCs with age and diminishing the long-term reconstitution of hematopoiesis in a competitive transplantation assay. In addition, ROS levels in HSC were elevated, and maintenance of quiescence was also impaired (Miyamoto *et al.*, 2007). These results were reproduced by FoxO1, FoxO3, and FoxO4 triple deletion in the adult hematopoietic system (Tothova *et al.*, 2007), which showed defective self-renewal, a shift toward the myeloid lineage, and increases in ROS that correlated with changes in expression of genes that regulate ROS. Importantly, treatment of the deleted mice *in vivo* with the antioxidative agent *N*-acetyl-L-cysteine reverted the FoxO-deficient HSC phenotype. Collectively, these data suggest that there is a subset of ROS genes that are regulated by FoxO proteins in the HSC compartment and that these genes function by reducing ROS levels and thereby removing any potentially deleterious effects on HSC survival and function.

Interestingly, the phenotype in FoxO-deficient mice is observed in upstream components of the PI3K/AKT/mTOR pathway, as in phosphatase and tensin homolog (PTEN)-deficient HSCs (Yilmaz *et al.*, 2006). PTEN acts by dephosphorylating phosphatidylinositol (3,4,5)-trisphosphate (PIP3) and is a tumor suppressor and negative regulator of mTOR signaling which prevents cell cycle progression. The fact that the mTOR inhibitor rapamycin could revert the phenotype of PTEN-deficient HSCs suggests that mTOR signaling may be involved in the HSC phenotype (Chen *et al.*, 2009). mTOR is a serine/threonine (Ser/Thr)-protein kinase that exists in two independent multiprotein-containing complexes, mTORC1 and mTORC2, and which are generally activated under conditions of nutrient availability. That is, mTORC1 is an energy sensor, and its expression is known to increase with age in HSCs, where it may also act as an attenuator of autophagy (Nicklin *et al.*, 2009). In young HSCs, conditional deletion of PTEN leads to indirect activation of mTOR, which causes a progeria-like phenotype and depletion of HSCs (Magee *et al.*, 2012; Kalaitzidis *et al.*, 2012). Overall, these studies suggest that either increased or decreased mTORC1 levels result in diminished capacity for HSC function and that careful regulation of mTOR by hematopoietic growth factor/cytokine signaling mediates self-renewal under regenerative conditions. Calorie restriction can attenuate mTORC1 signaling and other proteins associated with calorie restriction and metabolic effects in HSCs and tissue including HDACs. Both Sirt1 and Sirt3 HDACs have been shown to have roles in HSC function with age, whereby deletion of Sirt1 in adult HSCs increases HSC proliferation and DNA damage, whereas Sirt3 controls the activity of the mitochondrial enzyme acetyl co-enzyme A synthetase 2 (AceCS2) and electron transport chain complex 1 in mitochondria (Roth *et al.*, 2013). Deletion of Sirt1 therefore leads to loss HSC populations capable of long-term hematopoiesis (Singh *et al.*, 2013), whereas the metabolic consequences of Sirt3 deletion greatly diminish HSC function, while its up-regulation in aged HSCs improves their regenerative functions (Brown *et al.*, 2013).

Although the overall effects are modest compared to similar results in the other model SC systems, knockdown or deletion of p16^{INK4a} in HSCs ameliorates at least some of the age-associated phenotypes such as increased HSC number and aberrant self-renewal capacity, which agrees with the results reported in satellite cells (Janzen *et al.*, 2006; Sousa-Victor *et al.*, 2014). Similar roles for proteins that also function in these processes, including p53, the anti-apoptotic members of the BCL-2 family and the recently identified B-cell-activating transcription factor (BATF), have been proposed (Nitta *et al.*, 2011; Wang *et al.*, 2012). In the accelerated aging p53^{-/-} mice, which express a truncated p53 but are also haploinsufficient for 24 genes upstream of p53, animals show reduced lifespan, and less self-renewal and differentiation potential of HSCs (Donehower, 2009). In another model, the so-called super p53/p19^{ARF} mice, which have additional p53 and p19^{ARF} alleles, mice showed longer lifespan, perhaps due to reduced proliferation and maintenance of stem cell functionality at more optimal levels in the presence of a more robust ARF-p53 pathway (Matheu *et al.*, 2007). Overall, this suggests that an overactive p53 inhibits stem and progenitor cell function, whereas if properly regulated and boosted by increased ARF expression, it may have beneficial effects on stem cells later in life (Donehower, 2009). However, the full implication and biological relevance of these results in aging need to be determined. In this context, a recent publication has shown that functional decline of old HSCs were related to amplified levels of replication stress associated with cell cycle defects and chromosome breaks (Flach *et al.*, 2014). Mechanistically, a decreased expression of mini-chromosome maintenance (MCM) helicase components and altered dynamics of DNA replication forks resulted in residual replication stress on ribosomal DNA and formation of nucleolar-associated γ H2AX signals, which may account for HSC functional decline and open avenues for rejuvenation treatments (Flach *et al.*, 2014).

Epigenetic analysis has also revealed changes in old compared to young HSCs. It has been shown that genes associated with the myeloid lineage become hypomethylated with age, favoring transcription and therefore supporting the various observations of age-associated lineage skewing, whereas site-specific hypermethylation was observed at genes associated with the PRC2 complex (Beerman *et al.*, 2013; Bocker *et al.*, 2011). It has also been demonstrated that replicative aging is distinct from chronological aging at the DNA methylation level, suggesting that this age-dependent preference for myeloid differentiation by HSCs is a product of the proliferative history of HSCs (Beerman *et al.*, 2013). The evidence for this is that HSCs that were cultured under moderate proliferative demands underwent site-specific hypermethylation at the PRC2 complex, accompanied by transcriptional repression (Chambers *et al.*, 2007), whereas after enforced proliferation of adult HSCs, there was a highly distinct methylation pattern. Systematic analysis of the transcriptome and epigenome also suggested a close correlation between the typical phenotype of aged HSCs, mainly increased self-renewal, diminished differentiation potential, and biased preference for myeloid differentiation, and epigenetic alterations (Sun *et al.*, 2014). Briefly, age was associated with an increase in H3K4me3, particularly on genes associated with stem cell self-renewal and loss of differentiation capacity, which is similar to reports from

satellite cells in muscle, where H3K4me3 length was also observed to increase with age (Liu *et al.*, 2013). These age-related changes were also suggestive of decreased TGF β signaling, in conjunction with decreases in the phosphorylation and/or expression of various downstream effectors such as the various Smad proteins (Sun *et al.*, 2014).

Concluding Remarks

Organs and tissues deteriorate progressively with age. In recent years, it has become evident that as organisms age, tissue-resident stem cells also deteriorate, as illustrated by their impaired capacity to respond to an insult or maintain homeostasis. Extrinsic changes in the environment as well as cell-autonomous alterations with aging account for the age-associated deterioration of stem cell functions. Additional studies will be needed to better understand the specific extrinsic factors associated with defective stem cell-dependent tissue repair in aged individuals and the rejuvenation of old stem cell capacity by a young environment. Likewise, it will be necessary to identify how aging directly impacts on stem cell-intrinsic functions and whether these can be linked to epigenetic patterns. Further understanding of these signaling networks operating on stem cells will facilitate strategies to slow down or reverse the onset of aging on tissues and organs and to improve their repair in aging individuals.

Introduction: Regulation of Gene Expression in Stem Cells

All cell types that compose tissues and organs of adult multicellular organisms arise early in embryonic development as a result of lineage commitment and functional specialization of embryonic stem cell (ESC)-derived cellular populations present in the three initial germ layers – ectoderm, endoderm, and mesoderm (Murry and Keller, 2008). ESCs are pluripotent, self-renewing cells derived from the inner cell mass (ICM) of the developing blastocyst (Rossant, 2008). Pluripotency is the capacity of a single cell to generate all cell lineages of the developing and adult organism. Self-renewal is the ability of a cell to proliferate in the same state. The elucidation of the mechanisms by which ESCs self-renew while retaining their pluripotency has been a major challenge in the last decade and led to the discovery of the regulation of gene expression in ESCs by functionally relevant changes to the genome that do not involve a change in the nucleotide sequence – collectively referred to as epigenetic regulation of gene expression.

The complete mapping of the human genome and the advent of sophisticated technologies for chromatin analysis coupled with high-throughput DNA sequencing has made unprecedented genome-wide studies possible. These efforts have elucidated the dynamic changes of the epigenetic landscape that regulate gene expression. These studies have revealed the epigenetic networks that confer upon ESCs their unique property to undergo indefinite self-renewing while remaining poised to adopt a complete range of lineages and subsequent differentiation into specialized cell types in response to developmental cues. The progressive lineage restriction of human ESCs (hESCs) in response to developmental cues is achieved through a complex interplay between epigenetic and genetic factors, which establish unique gene expression profiles that underlie cell type-specific biological activities. A key aspect of this interplay relates to the simultaneous activation and repression of distinct clusters of genes, which ultimately direct lineage specification and functional specialization of ESC progeny (Orkin *et al.*, 2008). Execution of this program is coordinated by the combinatorial activities of transcriptional activators, cofactors, and the recently discovered noncoding RNAs, which generate discrete epigenetic signatures, consisting of specific patterns of histone modifications, changes in chromatin structure, and DNA methylation (Bibikova *et al.*, 2008). These activities are superimposed upon and tightly interconnected with the genome and are globally referred to as the ‘epigenome.’

The knowledge generated from ESC biology has been recently extended to induced-pluripotent stem cells (iPSCs), which are derived from the reprogramming of somatic cells into pluripotent cells that resemble ESCs and currently hold great promise in the field of regenerative medicine

(Wu and Hochedlinger, 2011; Jaenisch and Young, 2008). Moreover, concepts and principles generated from these studies have been extended to adult stem cells, whose intrinsic pluripotency is restricted to a limited number of cell types dictated from the germ layer derivation and organs and tissues in which they reside (Wabik and Jones, 2015).

Effectors and Mechanisms of Epigenetic Regulation of Gene Expression in ESCs

The interplay between distinct complexes endowed with specific enzymatic activities is required to set the unique epigenetic landscape that directs the gene expression in every cell type, including ESCs. This interplay impacts on few basic regulatory mechanisms that include histone modifications, changes in chromatin structure, generation of noncoding ncRNA, and DNA methylation (Young, 2011). When considered at the genome-wide level, these events can produce such a variety of ‘epigenetic signatures’ that regulate every cell type-specific profiles of gene expression through developmental stages.

The seminal discovery of mammalian nuclear transcriptional ‘coregulators’ that are able to enhance the activity of transcription factors, by virtue of their enzymatic activity (Yang *et al.*, 1996), provided a landmark framework that paved the way to the identification of additional enzymatic activities that regulate gene expression at the epigenetic level by promoting posttranslational modifications of histones. In particular, the histone tails that protrude from the fundamental unit of chromatin – the nucleosome (see below for more detailed description) – undergo extensive posttranslational modifications (Tessarz and Kouzarides, 2014), including lysine acetylation, methylation, arginine methylation, and serine/threonine phosphorylation. Additional histone modifications include SUMOylation and ubiquitination. Enzymes that catalyze the posttranslational modifications of histones have been referred to as ‘writers’ of a ‘code’ that indicates whether gene expression is activated or repressed. The activity of histone ‘writers’ is countered by enzymes endowed with an opposite function – called ‘erasers’ – that remove histone modifications. The dynamic combination of different histone modifications provides a code that is read by several enzymatic complexes – the ‘readers’ which include the ‘writers’ themselves and the chromatin remodelers (Wang *et al.*, 2004) – see below for further details.

Enhancer Activation and Developmental Competence

One of the first ‘writers’ to be discovered were the histone acetyltransferases p300/CBP and PCAF, which have been originally found to promote transcription by virtue of their intrinsic acetyltransferase (HAT) activity and ability to interact

with transcription factors (Yang *et al.*, 1996; Ogryzko *et al.*, 1996; Bannister and Kouzarides, 1996). In particular, p300/CBP-mediated lysine acetylation of histones establishes cell type-specific patterns of localized 'hyperacetylation' across the genome in response to external cues. Following the discovery of HATs, a growing number of proteins belonging to multi-protein complexes and endowed with specific enzymatic activities, have been discovered and characterized. The availability of chromatin-immunoprecipitation (ChIP) and ChIP-related techniques coupled to high-throughput next-generation sequencing (ngs) has allowed genome-wide mapping of key epigenetic changes that are generated by the activity of these complexes and that regulate gene expression in ESCs, as well as in somatic cells. The growing number of ngs data have been collected and analyzed within international consortium networks, such as ENCODE, that provide a dynamic, updated illustration of the epigenome in human cells. This framework has permitted the identification 'epigenetic signatures' of functional domains of the genome of hESCs that are summarized below.

In general, histone hyperacetylation marks domains of the genome that are permissive for transcription, and *vice versa* hypoacetylation correlates with transcription silencing. However, acetylation of one particular lysine (K27) of histone H3 (H3K27Ac) by p300 has been instrumental for the identification of active enhancers (Visel *et al.*, 2009; Creyghton *et al.*, 2010). Enhancers define short (about 50–1500 base pairs) elements of the genome that are targeted by sequence-specific transcriptional activators to activate transcription of genes located up to 1 Mbp (1 000 000 base pairs) upstream or downstream from the start site of the target gene. There are hundreds of thousands of enhancers in the human genome and their combinatorial activation gives rise to unique collections of enhancers that support cell type-specific patterns of gene expression (Andersson *et al.*, 2014). Indeed, enhancers mediate both spatial and temporal control of development by inducing transcription in certain cells types, while repressing it in other cells – a process also known as developmental competence (Wang *et al.*, 2015). Thus, it is believed that activation of discrete subsets of enhancers is highly predictive of biologically different transcriptional outputs in ESCs. Inactive enhancers are typically marked by H3K4monomethylation (H3K4me1), a modification that also persists after activation and is therefore used as a marker of enhancer identification. In response to developmental cues, binding of transcription factors to specific sequences within certain enhancers induces H3K27Ac, by recruitment of p300 and possibly other HATs. These transcription factors are defined as pioneers, since they preset the chromatin at previously silent enhancers for subsequent activation by other transcriptional activators. In self-renewing ESCs, the cooperative interactions among the ESC-specific transcription factors Oct4, Sox2, and Nanog within specific enhancers maintain the expression of genes that promote stem cell properties, as long as ESCs are exposed to conditions that maintain the stem cells in an undifferentiated state. By contrast, once exposed to developmental cues, enhancers binding by lineage-specific transcription factors, and simultaneous depletion of Oct4, Sox2, and Nanog from stem cell-specific enhancers, activate gene expression toward differentiation into specific lineages (Xie and Ren, 2013).

Promoter Bivalency and Maintenance of Pluripotency

While enhancer activation is a key mechanism that determines whether ESC proliferate as undifferentiated cells or commit toward a differentiated cell type, distinct posttranslational histone modifications at promoters are important to establish the chromatin structure that permits ESCs to maintain pluripotency. Promoters define DNA elements that initiate transcription of a particular gene, whose transcription start-sites are located immediately downstream. The two regulatory histone marks that influence chromatin structures at promoters in ESC are histone 3 lysine4 tri-methylation (H3K4me) and histone 3 lysine27 tri-methylation (H3K27me3). They are catalyzed by distinct types of methyltransferase-containing complexes and have a different impact on chromatin structure and gene transcription (Ringrose and Paro, 2004; Schuetten-gruber *et al.*, 2007). H3K27me3 is typically catalyzed by the enzymatic subunit of the Polycomb Group (PcG) – Enhancer of Zeste (EzH2). H3K4me3 is catalyzed by a battery of histone methyltransferases (HMTs) that show functional and structural analogies to the enzymatic complex Trithorax group (TrxG), originally identified in *Drosophila melanogaster*. In adult somatic cells, H3K27me3 at promoters silences the transcriptional activity of downstream genes, while promoters of transcriptionally active genes are typically enriched in H3K4me3. Thus, the antagonistic activities of PcG and TrxG define the promoter configuration that determines the activation/repression of specific subsets of genes during development that ultimately support the formation of various types of differentiated cells. In ESCs, the simultaneous presence of H3K4me3 and h3K27me3 has been observed at most of the developmental genes. This is considered a unique signature of pluripotency, and it is also referred to as 'bivalency' (Azuara *et al.*, 2006; Bernstein *et al.*, 2006; Boyer *et al.*, 2006). Bivalent promoters are considered 'poised' for either activation (by loss of H3K27me3) or repression (by loss of H3K4me3) in response to developmental cues. As such, promoter bivalency is considered a key epigenetic mechanism by which ESC can proliferate while retaining their pluripotency. Of note, bivalent promoters are typically occupied by 'paused' Polymerase II, which is bound at the TSS of the downstream gene, but is not able to initiate transcription. Resolution of promoter bivalence by developmental signals either promotes predominant H3K4me3 and Pol II elongation, to activate lineage-specific gene expression, or generate local enrichment of H3K27me3, which inhibits transcription, at least in part, by restraining poised RNA Pol II (Stock *et al.*, 2007; see Figure 1).

Chromatin Remodeling

An important mechanism by which histone modifications can change the structure of the chromatin in enhancers and promoters is the chromatin remodeling, which in turn alters the nucleosome architecture and frequency across the genome. Nucleosomes are the basic units of chromatin and consist of 146 base pairs of DNA wrapped around a core octamer of two copies each of four different types of histone – H2A, H2B, H3, and H4 (Kornberg and Thomas, 1974). Nucleosomes are distributed throughout the genome as repeating arrays spaced by linker DNA and histones. The DNA packaging into

Figure 1 Schematic representation of the chromatin transitions at regulatory elements in stem cells. Top shows a typical 'bivalent' promoter in embryonic stem cells that can be resolved in three different transcriptional outcomes (bottom): silencing by repressive chromatin (left), activation by permissive chromatin (middle), and perpetuation of bivalency by poised chromatin (right).

nucleosomes provides a natural barrier against the access of DNA-binding protein, to allow a control to the binding of transcriptional activators to their DNA-binding motifs. Indeed, displacement or mobilization of nucleosomes is a key mechanism that controls the activation of certain subsets of genes by tissue-specific transcriptional activators during hESC differentiation. Likewise, dynamic redistribution of nucleosomes can repress gene expression by occluding other transcription factors access to DNA. Given that the large majority of the genome is covered by nucleosomes, an outstanding question relates to how transcriptional activators access their DNA-binding motifs. Recent work has revealed that a limited number of sequences of DNA are exposed within the nucleosome structure and these sequences are recognized by pioneer transcription factors, which appear to initiate the process of chromatin remodeling, followed by nucleosome displacement, exposure of full sequences of DNA available for binding of additional transcription factors that cooperate with other components of the transcriptional machinery to activate transcription (Zaret and Carroll, 2011). This sequence of events occurs in enhancers and promoters of ESC, and depending on the identity of the transcriptional activators that access to the DNA, can generate a transcriptional output that directs distinct lineages.

Chromatin remodeling occurs through an ATP-dependent activity of specialized multi-protein complexes (Clapier and Cairns, 2009). Among them SWI/SNF chromatin remodeling complexes are of particular importance (de la Serna *et al.*, 2006). These complexes are highly dynamic in their composition, which varies depending on the cell type and developmental stage. SWI/SNF complexes typically contain one

enzymatic subunit – either the ATPase Brahma (Brm) or Brg1 – and a collection of Brg1/Brm-associated factors (BAFs) (Ho and Crabtree, 2010). SWI/SNF recruitment to specific DNA elements is mediated by interactions with sequence-specific transcriptional activators and with certain histone modifications, such as histone acetylation (Clapier and Cairns, 2009). SWI/SNF-mediated chromatin remodeling at promoters or enhancers facilitates or reduces the access of transcriptional components to DNA sequences with resulting positive or negative effects on gene activity. An ESC-specific SWI/SNF complex (called esBAF) has been purified and shown to be associated with promoters of genes under the control of Oct4, Sox2, and Nanog. It appears that depending on the presence of specific core subunits, the SWI/SNF complex supports ESC maintenance or differentiation into specific cell types (Ho and Crabtree, 2010; Albini *et al.*, 2013). In response to developmental cues and generation of the three germ layers, different progenitor cells from ectoderm, endoderm, and mesoderm show distinct SWI/SNF complexes with a specific combination of components that imparts cell type-specific patterns of chromatin remodeling, in concert with tissue-specific transcriptional activators. Importantly, it appears that in undifferentiated ESCs SWI/SNF-mediated chromatin remodeling is implicated more in establishing repressive chromatin to prevent differentiation; by contrast, during ESC differentiation SWI/SNF activity is required to remodel the chromatin at active loci (Saladi and de la Serna, 2010). Given the heterogeneity in SWI/SNF composition and dynamic exchange of subunits, it is likely that the ability of repressing or activating transcription depends on the presence of specific subunits that allow proper response to extrinsic signals.

DNA Methylation

Another important layer of epigenetic regulation of transcription is provided by DNA methylation, which cooperates with posttranslational modifications of histones and changes in chromatin structure to regulate genes expression in ESCs. Mechanistically, DNA methylation contributes to establish and maintain repressive domains through the genome. DNA methylation is essential for mammalian development and is catalyzed by DNA methyltransferases, the large majority of which are expressed in ESCs.

In ESCs, DNA demethylation triggers a sequence of events that ultimately resolve the equilibrium between the totipotency of the zygote and the pluripotency of the embryo. DNA demethylation in the zygote is required to erase existing epigenetic signatures inherited from the gametes, but at the same time resets the epigenetic identity toward the acquisition of lineage commitment upon developmental cues. Although a large part of the genome (60–80% of all CpG dinucleotides) is methylated in ESCs (Meissner, 2010), ESCs can be established and maintained in the absence of DNA methyltransferases and DNA methylation. Still, DNA methyltransferase-deficient ESCs show an impaired differentiation potential (Jackson *et al.*, 2004), possibly due to the incomplete silencing of Oct4 and Nanog during differentiation (Feldman *et al.*, 2006). Indeed, ESCs show an increased global methylation during cellular differentiation, with cell type-specific patterns of methylation. The gain of methylation observed during ESC differentiation mediates silencing of pluripotency genes, but is also required to prevent the inappropriate expression of genes of alternative lineage. As such, DNA methylation contributes to narrow the repertoire of lineage-specific gene expression that specifies the cellular identity of ESC-derived progeny (Nazor *et al.*, 2012). Likewise, demethylation at pluripotency genes is required for induced pluripotency in somatic cells. Interestingly, methylation/demethylation events cooperate with histone modifications to establish promoter bivalency, but also occur outside promoter sequences, as dynamic changes in DNA methylation have been observed at distal gene sequences and intronic regions (Meissner *et al.*, 2008).

Noncoding RNA

The contribution of noncoding RNA (ncRNA) to development and ESC differentiation has been established by several recent studies, which have revealed the interplay between ncRNA and epigenetic factors in modulating the transcriptional outputs of ESCs. Initial hints derived from showing the cooperation between PcG and ncRNA studies on X inactivation (Lee, 2009). Indeed, a long list of ncRNA species (including microRNA and long-noncoding RNA – lincRNA) has been implicated in the control of ESC state and differentiation.

MicroRNAs are short RNA molecules that bind to complementary sequences on messenger RNA and block expression of a gene (Bartel, 2009). miRNAs contribute to both maintenance of pluripotency in ESC and differentiation toward different lineages. The first evidence of a role of miRNA in ESCs was provided by the observation that deficiency in the miRNA-processing enzymes Dicer and DCGR8 resulted in defects in differentiation and proliferation (Kanellopoulou *et al.*, 2005;

Murchison *et al.*, 2005; Wang *et al.*, 2007). Further studies revealed that the core regulators Oct4/Sox2/Nanog promote the generation of miRNAs essential for maintenance pluripotency during ESC proliferation while repressing lineage-specific miRNA (Marson *et al.*, 2008). Among the miRNAs that control ESC identity, pluripotency and differentiation potential, the mir-290–295 cluster appears of special importance (He *et al.*, 2005; Kanellopoulou *et al.*, 2005; Murchison *et al.*, 2005; Wang *et al.*, 2007), as forced expression of ESC-specific microRNA (miR-291, miR-294, and miR-295) in somatic cells enhances the efficiency of induced pluripotency.

Likewise, a broad spectrum of lincRNAs of various lengths that are transcribed bidirectionally by RNA polymerase II from different elements of the genome, including enhancers and promoters, has shown to contribute to the epigenetic regulation of ESCs (Zaratiegui *et al.*, 2007; Hu *et al.*, 2012). In particular, an emerging theme regards the ability of these ncRNAs to mediate PcG-dependent gene silencing (Zhao *et al.*, 2008). PcG complexes show an affinity for lincRNA of about 200–1200 nucleotides that are often transcribed from genes occupied by PcG complexes and that facilitate or stabilize the recruitment and the activity of PcG complexes at specific loci in the genome of ESCs (Kaneko *et al.*, 2014).

Overall, the field of ncRNA-mediated regulation of the epigenetic landscape and transcription in ESC is rapidly evolving and the functional connection between RNA biology and epigenetics will be further elucidated by future studies.

Epigenetic Signatures and Control of Nuclear Architecture in ESCs

In ESCs, the pluripotent state is established and maintained by the expression of the core transcription factors Oct4, Sox2, and Nanog. These core transcription factors positively regulate their own promoters, thereby providing a feed-forward loop. Moreover, they co-occupy the regulatory regions of genes that maintain the ESC state, while repressing the expression of lineage-specific genes. Thus, the expression levels of ESC core transcription factors determine whether ESC proliferate in their undifferentiated state or differentiate into specific cell types (Boyer *et al.*, 2005). This regulatory circuit likely explains why forced, ectopic expression of these factors in somatic cells can reprogram the genome toward pluripotency – the key concept that inspired the seminal discovery of induced-pluripotent cells by Yamanaka and colleagues (Takahashi and Yamanaka, 2006; Jaenisch and Young, 2008). Additional factors, such as c-Myc, can also facilitate activation of this program by stimulating gene expression. Indeed, while Oct4, Sox2, and Nanog are involved in RNA polymerase II recruitment, c-Myc stimulates the release of Pol II pause to activate genes implicated in ESC proliferation and self-renewal (Cartwright *et al.*, 2005). An essential mechanism that maintains ESCs in their undifferentiated state is provided by the presence of factors that inhibit the signals that stimulate differentiation (Pera and Tam, 2010). Among these inhibitory factors, LIF, Wnt, and ligands of the TGF- β /BMP signaling pathway appear particularly important as they activate transcription factors, such as Stat3, Tcf3, and Smad1 that co-occupy enhancers bound by Oct4, Sox2, and Nanog.

In contrast, upon removal of these inhibitory factors, differentiation cues extinguish the network of ESC core transcription factors and promote the expression of tissue-specific transcriptional activators, which direct the transcriptional output toward the generation of ESC-derived lineages within the three germ layers, ultimately promoting the formation of embryoid bodies.

How can ESCs integrate such a variety of stimuli into specific responses (e.g., stemness or differentiation) and how can they be instructed to maintain the transcriptional profiles evoked by developmental cues? The answer probably resides in the plasticity of the nuclear architecture, which can adapt a vast combination of long-range interactions between functional domains of the genome. The recent availability of techniques based upon chromosome conformation capture or 3C, has permitted high-throughput analyses of the organization of chromosomes, and has revealed functionally relevant interactions between functional elements of the genome. These long-range interactions are mediated by a class of transcriptional coregulators, called mediators, and by other specialized proteins, such as cohesin and CTCF and lead to the formation of topological domains (TDs). Recent studies have revealed that TDs often consist of loops by which enhancers and promoters establish physical contacts and share common epigenetic regulators (Jin *et al.*, 2013). This explains why p300 occupies the most active enhancers and promoters in ESCs (Chen *et al.*, 2008b) and suggests a mechanism by which developmentally competent enhancers resolve promoter bivalency and activate the expression of lineage-specific genes during ESC differentiation. These studies have been extended also to ESCs, revealing the importance of TAD formation during lineage commitment (Dixon *et al.*, 2015). Likewise, Oct4/Sox2/Nanog-bound enhancers can interact with promoters of active genes in the core regulatory circuitry of undifferentiated ESCs (Kagey *et al.*, 2010). Of note, core pluripotency or tissue-specific transcription factors, cofactors and mediators often co-occupy enhancers with signaling transcription factors (such as TGF β -activated SMADs), thereby integrating developmental cues with epigenetic regulators and the transcriptional machinery (Mullen *et al.*, 2011). It has been recently proposed that the formation of super-enhancers (e.g., enhancers enriched in specific transcriptional activators and mediators) drives the nuclear architecture and transcriptional outputs. Finally, an additional layer of tridimensional regulation of the nuclear landscape is provided by the nuclear position of TDs, with nuclear periphery being generally associated with transcriptional repression.

Overall, the ESC transition from pluripotency to lineage commitment is underlined by an extensive reconfiguration of the epigenetic landscape, in which coding and noncoding elements of the genome cooperate to establish epigenetic signatures leading to regulatory structures that coordinate the expression of different subsets of genes in response to developmental cues.

Epigenetic Control of Quiescence/Stemness and Lineage Determination in Adult

Stem cell compartments in adult mammalian organisms are required for the homeostatic maintenance and repair of mature tissues. Adult stem cells are endowed with the ability to

generate cells of the tissue in which they reside, and self-renew (i.e., generate more copies of themselves in order to maintain the stem cell compartment). They are distinct from ESCs as they are not pluripotent (i.e., not able to generate all the tissues of the body or contribute to all the tissues upon implantation into the blastocyst).

Adult stem cell function is influenced by both intrinsic and extrinsic factors. The 'stem cell niche,' originally defined by Schofield (1978), is the immediate microenvironment to which stem cells are exposed to and it is key in supporting and instructing stem cell behavior through secreted factors, extracellular matrix (ECM) components, and cell-cell communications. For example, polarity within the niche, i.e., different regions of a stem cell are exposed to different signals, contributes to determining stem cell division mode, asymmetric or symmetric. Integration of microenvironmental signals leads to changes in the epigenome of a cell, resulting in a different transcriptional output. While in high turnover tissues, such as blood and epithelia, they actively generate progeny to maintain tissues, in low turnover ones such as skeletal muscle and nervous system they only rarely proliferate. In spite of these differences, there is significant conservation across different adult stem cell compartments.

One key feature is 'cellular quiescence.' Most adult stem cells at any given time exist in a quiescent state, defined as a reversible nonproliferative state from which stem cells can emerge in response to stress or tissue injury, start dividing and self-renew as well as generate committed progeny to contribute to tissue repair. Significant effort in the last decades has investigated the epigenetic landscape associated with these distinct states, quiescence, activation, and differentiation, and has provided critical insights into how the transitions between these states are dynamically regulated.

Skeletal Muscle Stem Cells

Satellite cells (SCs) are tissue-resident muscle stem cells required for postnatal growth and regeneration of skeletal muscle (Brack and Rando, 2012). They reside in their anatomical niche, within the space between the myofiber membrane and the surrounding basal lamina (Mauro, 1961). Upon injury or stress they undergo activation, enter the cell cycle and divide to generate both committed progenitors that directly contribute to the repair of injured muscles and copies of themselves that replenish the pool of reserve SC. SC can be isolated from tissues by enzymatic digestion and fluorescence-activated cell sorting (FACS) based on cell surface markers.

Recent studies have compared global epigenetic marks in quiescent and activated SC, and shown that quiescent SC exhibit a high content of the bivalent domains, coexistence of both activating and repressive marks on the same gene (i.e., coexistence of H3K27me3 and H3K4me3), typically observed in the chromatin of ESCs and indicative of the stem cell identity (Liu, *et al.*, 2013). This profile is thought to indicate poised genes ready to be activated, suggesting a high degree of plasticity of this cellular state. Interestingly, these signatures are progressively lost upon SC activation, indicating a progressive restriction in potency upon activation of the myogenic program and terminal differentiation. Work from the Rando's

group identified miRNAs as major regulators of SC quiescence. Indeed, by conditional genetic deletion of Dicer, the RNA processing enzyme responsible for generating mature miRNA by cleavage of per-miRNA, they show that SC lose their ability to maintain quiescence. They further identify miR489 as a miRNA required for maintenance of SC quiescence, through the regulation of the oncogene DEK (Cheung *et al.*, 2012). Recent studies from Sartorelli's lab have revealed important metabolic features that distinguish quiescent MuSC from the activated, committed progeny and are conferred by the activity of a key epigenetic regulator – the histone deacetylase SIRT1 (Ryall *et al.*, 2015). These studies showed that quiescent MuSC mostly rely on fatty acid oxidation; however, upon activation, proliferating MuSC experience a metabolic switch to glycolysis – a 'metabolic reprogramming' that causes a decrease in intracellular nicotinamide adenine dinucleotide (NAD) (+) and consequent inhibition of SIRT1, ultimately leading to elevated H4K16 acetylation and activation of muscle gene transcription.

Upon stress or injury, several signals emanating from the microenvironment, including inflammatory, endothelial and mesenchymal cells, contribute to the activation of SC and their transition to the progenitor stage. For example, Tumor necrosis factor (TNF) activates p38alpha, which simultaneously signals to PgC to repress Pax7 and to the SWI/SNF complex to promote myogenic differentiation (Palacios *et al.*, 2010; Simone *et al.*, 2004). Conditional deletion of the enzymatic subunit of PRC2, Ezh2, induces a reduction in SC numbers, reduced muscle mass and defects in tissue repair, indicating that Ezh2 regulates SC self-renewal and proliferation (Juan *et al.*, 2011). Finally, an increasing level of complexity in the epigenetic regulation of SC is emerging from the recent identification and characterization of lncRNA, which promote chromatin modifications that regulate the activation of the myogenic program (Cesana *et al.*, 2011; Lu *et al.*, 2013; Anderson *et al.*, 2015; Mousavi *et al.*, 2013).

Hematopoietic Stem Cells

Hematopoietic stem cells (HSC) reside in the bone marrow and are responsible for the generation of all the lineages of the blood, including erythrocytes, platelets, myelocytes, and lymphocytes, throughout the life of an organism. HSC immediate microenvironment, the bone marrow niche, is composed by multiple cell types, including endothelial, osteoblastic, and stromal cells that emanate signals that play an important role in determining HSC behavior *in vivo*. In mice, HSC are identified and isolated by cell surface markers as Lineage-Sca1 + ckit + or CD150 + CD48- cells (Oguro *et al.*, 2013).

Epigenetic analysis revealed that disruption of DNA methylation through manipulation of DNA methyltransferases impaired HSC function. For example, deletion of Dnmt1, required for the maintenance of DNA methylation, induces premature differentiation, suggesting that Dnmt1 acts to preserve stemness and prevent premature differentiation in the stem cell compartment (Broske *et al.*, 2009; Trowbridge *et al.*, 2009). Conversely, conditional deletion of Dnmt3a, responsible for de novo DNA methylation, resulted in increased HSC numbers and impaired differentiation (Challen

et al., 2012). This is thought to take place through the requirement to repress self-renewal genes before terminal differentiation. HSC also possess high levels of bivalent histone marks, which is progressively reduced during differentiation (Attema *et al.*, 2007). Conditional deletion or mutations of Bmi1, a component of the Polycomb Repressive Complex PRC1, leads to decreased HSC self-renewal, while its over-expression induces self-renewal and symmetric expansion of HSC (Park *et al.*, 2003). While deletion of Ezh1, component of PRC2 complex, impairs HSC self-renewal and prevents cellular senescence (Hidalgo *et al.*, 2012), mutations of PRC2 components Ezh2, Eed, and Suz12 enhanced HSC function, although they seem to act in a developmental stage-specific manner (Majewski *et al.*, 2008). Consistent with these findings, treatment of animal models with Trichostatin A (inhibitor of HDAC) or 5-azacytidine (inhibitor of Dnmt) enhanced HSC self-renewal, indicating the critical role of these epigenetic modifiers in the regulation of HSC function (Chung *et al.*, 2009).

Recent studies have also highlighted a critical role of miRNAs in regulating HSC function. For example, conditional deletion of the RNA processing enzyme Dicer resulted in decreased HSC number and increased rate of apoptosis (Guo *et al.*, 2010) and deletion of lncRNAs Xist and H19 affect HSC survival and quiescence, respectively (Yildirim *et al.*, 2013; Venkatraman *et al.*, 2013).

Neural Stem Cells

Neural stem cells (NSC) resides in the subgranular zone (SGZ) of the dentate gyrus region of the hippocampus, and also in the subventricular zone (SVZ), a layer of cells in the lateral zone of the lateral ventricle of the brain. The NSC niche comprises microglia, astrocytes, and vasculature. The nervous system is a low turnover tissue, and for long time it was believed that the brain was a completely postmitotic tissue devoid of stem or progenitor cells. NSC are classically isolated by enzymatic digestion of the brain followed by culture expansion. NSC express transcription factors Sox2 and Mash, intermediate filament gene Nestin and the astrocytic marker glial fibrillary acidic protein (GFAP) (Suh *et al.*, 2007; Song *et al.*, 2012). Dynamic DNA methylation has been associated with NSC differentiation. In fact, expression levels of DNMT1 and DNMT3a are transiently increased during early differentiation, and progressively reduced at later stages (Singh *et al.*, 2009). This could be associated to the need to silence self-renewal genes in order to promote the transition to the progenitor stage and later mature neurons. Consistent with these observations, Dnmt3a^{KO} mice exhibit impaired adult neurogenesis (Wu *et al.*, 2010). Similar pattern of expression is observed for the methyl-CpG-binding protein MBD1, which binds methylated gene promoters and induces transcriptional repression (Singh *et al.*, 2009), and knockout animal models also exhibit impaired adult neurogenesis (Zhao *et al.*, 2003), indicating the dynamic transition during early differentiation is a critical step for chromatin modification to activate the differentiation program, and at the same time select which cell fate NPC will adopt. For example, MBD1 represses genes involved in self-renewal, such as FGF2, enabling NSC

to proceed toward neurogenic differentiation. Conversely, MeCP2, another MBD protein, is involved in neuronal maturation, indicating stage-specific effects of different chromatin regulators (Smrt *et al.*, 2007). Changes in histone modifications and chromatin remodeling are also critical for proper adult neurogenesis. For example, treatment with HDACi sodium butyrate, valproic acid, or suberoylanilide hydroxamic acid (SAHA) promoted NSC lineage-specific neuronal differentiation at the expense of self-renewal (Hsieh *et al.*, 2004). Bmi1 is required for adult NSC self-renewal *in vivo* and its expression increases neurosphere formation *in vitro* (Fasano *et al.*, 2009). Mll1 (mixed-lineage leukemia 1), a member of Trithorax group (trxG), is required for neurogenesis in the mouse postnatal brain, as its genetic deletion severely impaired neurogenesis (Lim *et al.*, 2009). This supports a model in which Mll1 is required to resolve key silenced bivalent loci in postnatal neural precursors to the actively transcribed state for the induction of neurogenesis. Finally, several miRNAs have been implicated in adult neurogenesis, including, among others, miR9, miR34a, miR124, miR125b, miR132, and miR137 (Fitzsimons *et al.*, 2014).

Plasticity of Adult Cell Fate

Pioneering studies in the 1950s by John Gurdon highlighted for the first time that the differentiated state is not fixed or irreversible. Indeed, when a nucleus from a somatic cell is transplanted into an enucleated oocyte (somatic cell nuclear transfer), factors in the oocyte cytoplasm are sufficient to reset the clock back and confer the somatic cell nucleus with properties of ESCs (Gurdon, 1962a,b). These studies provided the first evidence of plasticity of cell fate and in the last decades they enabled the cloning of entire organisms, such as Dolly the sheep (Wilmut *et al.*, 1997). More recently, the groundbreaking findings from Yamanaka's group that by manipulation of a small number of transcription factors, OCT4, SOX2, KLF4, and c-MYC, it is possible to reprogram adult cells to an embryonic state shed light on key regulators of gene expression (Takahashi and Yamanaka, 2006). Epigenetic changes associated with nuclear reprogramming include telomere re-elongation, DNA demethylation and modifications in chromatin composition and structure. These findings paved the way to revitalizing stem cell biology and iPSCs are a powerful tool for disease in a dish model, drug screening and potential cell replacement therapies.

The Skin Hair Follicle

The Hair Follicle Stem Cell Populations – A Series of Specialized Compartments with Varying Cell Fate Competences

Mammalian skin is capable of pronounced regeneration and undergoes turnover throughout the life of the organism. In mammals, the skin contains millions of hair follicles and harbors multiple populations of resident progenitor cells. The murine hair follicle has been particularly well studied. It undergoes repeated cycles of growth, regression, and rest throughout life. A pronounced regenerative capacity, coupled with its accessibility for experimental manipulation has led to significant advances in skin stem cell biology. In young mice, hair cycles are synchronized providing a tractable means to dissect the interactions between stem cells and their environment. Hair stem cells undergo repeated transitions between quiescence, activation, and subsequent acquisition of a differentiated cell fate coupled with stem cell self-renewal (Paus and Cotsarelis, 1999). Hair follicles contain distinct and spatially separated epithelial stem cells that possess unique molecular signatures that differentially contribute to the hair follicle during cycling and regeneration. Initial studies sought to identify stem cells by virtue of their predicted slow cell cycling, considered essential to maintain a reserve pool of progenitors. These initial investigations led to the identification of a reservoir of slow-cycling and label-retaining cells (LRCs) in a structure called the hair follicle bulge (Cotsarelis *et al.*, 1990). The bulge is located near the base of the hair follicle and remains intact throughout the hair cycle (Figure 1). Bulge cells express specific markers that have proven useful for their purification and dissection of different phases of bulge cell. For example, keratin 15 (K15) is expressed in undifferentiated and quiescent bulge keratinocytes and their transcriptional gene signature is similar to that of stem cells in other organs (Liu *et al.*, 2003; Morris *et al.*, 2004). CD34 is expressed by quiescent stem cells throughout the cycle, and purified CD34-positive bulge cells display clonogenic capacity (the ability to form a colony in a dish from a single cell) and self-renewal features of stem cells *in vitro* (Blanpain *et al.*, 2004). Bulge cells also express high levels of sex-determining region Y-box 9 (SOX9), which not only marks these cells but is functionally required for their maintenance (Kadaja *et al.*, 2014). The more proliferative cells in the lower portion of the bulge express the Leu-rich repeat-containing G protein-coupled receptor 5 (LGR5) and LIM homeobox protein 2 (LHX2) (Barker *et al.*, 2008). While this list of markers that identify bulge cells is not complete, what emerges is that these cells occupy a discreet and anatomically recognizable structure but retain a level of heterogeneity within that structure reflecting cell cycle and stem cell competence. When these

cells are purified by use of these markers and then engrafted into the skin of host mice, they are capable of reestablishing the hair follicle along with associated structures (Blanpain *et al.*, 2004). By use of genetic lineage tracing models, it has been shown that the bulge cells give rise to all the hair follicle structures and most of the associated structures including the bulge (Tumbar *et al.*, 2004). While the bulge cells are a clear example of an 'ideal stem cell' that gives rise to new hair follicles as well as self-renew, a significant amount of work has shown that the bulge cells are highly responsive to cells that lie in close vicinity and while these cells are derived from the bulge, they acquire additional stem cell potentials. Just below the bulge is the hair germ (Figure 1). The cells in the hair germ are derived from the bulge stem cells and while they have a similar molecular signature (i.e., they express K15, SOX9, LHX2, and LGR5), they are more proliferative (Greco *et al.*, 2009; Tornqvist *et al.*, 2010). Hair germ cells exhibit high

Figure 1 Generalized structure of the hair follicle during the resting phase of the hair cycle. The hair follicle consists of delineated anatomical compartments: the hair germ, bulge, isthmus, and infundibulum. The dermal papilla lies directly under the hair germ; sebaceous gland is attached to the side of the hair follicle. Each compartment contains different stem cells that are characterized by unique molecular signatures and different cell fate potentials.

levels of P-cadherin and GLI-Kruppel family member GLI1 (GLI1) that permit them to be distinguished from bulge cells (Greco *et al.*, 2009). Germ cells display remarkable multipotency and contribute to the entire hair follicle including bulge stem cells (Ito *et al.*, 2004). However, the hair germ cells are less clonogenic as compared to bulge stem cells *in vitro* (Greco *et al.*, 2009). The cells in the hair germ are the first to express genes that indicate stem cell activation and the first to proliferate at the beginning of a new hair regeneration cycle (Rompolas *et al.*, 2012). These observations suggest that a specific anatomical and lineage ordering exists in the hair follicle in which the bulges give rise to the hair germ, which in turn provides the bulk of the other skin structures consistent with the 'label-retaining cell' behavior of the bulge.

In addition to the bulge and germ cells, other subsets of specialized progenitors exist in defined anatomical compartments located above the bulge. The isthmus is situated between the bulge and the sebaceous gland (Figure 1). The cells in the isthmus differ from the bulge cells, as they do not express CD34 or K15 (Jensen *et al.*, 2008). The isthmus cells located close to the bulge display self-renewal properties, can regenerate the hair follicle, and may serve as a reserve stem cell population as well as contribute to wound healing (Brownell *et al.*, 2011). The central part of the isthmus can be identified on the basis of LGR6 and MTS24 expression and have been shown to contribute to the isthmus zone, epidermis, and sebaceous gland during homeostasis and mobilize to the epidermis following injury (Jensen *et al.*, 2008; Snippert *et al.*, 2010). The uppermost part of the isthmus contains cells that express MTS24 and while these cells display a gene expression profile inherent to progenitor or stem cells as well as proliferative and clonogenic capacity, their function remains unclear (Nijhof *et al.*, 2006). The sebaceous gland resides in the upper portion of the hair follicle (Figure 1) and serves an important role in lubricating and waterproofing the epidermis. B-lymphocyte-induced maturation protein 1 (BLIMP1)-positive cells near the gland opening can generate the sebaceous gland lineages (Horsley *et al.*, 2006). However, BLIMP1 is also widely expressed in differentiated epidermal and sebaceous gland cells and is not considered as a specific marker of sebaceous stem cells (Magnusdotir *et al.*, 2007). Leucine-rich repeats and immunoglobulin-like domain 1 (LRIG1) expression also marks sebaceous gland cells (Page *et al.*, 2013). Additional studies will be required to unveil whether cells from the bulge and isthmus contribute to the sebaceous gland or if it is maintained independently. The upper segment of the hair follicle that extends from the opening of the sebaceous gland duct to the epidermis is called infundibulum (Figure 1). The most upper part of this unit occupied by the cells that express stem cell antigen 1 (SCA-1). These cells have a unipotent capacity to regenerate interfollicular epidermis, and are thought to be keratinocyte progenitors (Jensen *et al.*, 2008).

Signaling between Follicle Stem Cells and Their Microenvironment

Bulge stem cells retain their lineage identity and progenitor potential to regenerate hair follicles after passaging *in vitro* and subsequent engraftment suggesting that either systemic or

local environmental clues are not required to maintain their proper function (Blanpain *et al.*, 2004; Toyoshima *et al.*, 2012). While the bulge cells can form a multitude of cell types as outlined above, they respond to multiple resident cell types including specialized dermal fibroblasts, adipocytes, muscle cells, and neurons (Plikus *et al.*, 2008; Brownell *et al.*, 2011; Fujiwara *et al.*, 2011). One key source of signals to the bulge is the dermal papilla, which is a mesenchymal niche that consists of a condensed group of dermal fibroblasts located at the base of a resting hair follicle (Driskell *et al.*, 2011). The dermal papilla cells are characterized by the expression of multiple markers including TBX18, Corin, SOX2, and CD133 (Enshell-Seijffers *et al.*, 2008; Driskell *et al.*, 2009; Grisanti *et al.*, 2013). The dermal papilla remains in close anatomical association with the follicle throughout the hair cycle and is essential for the activation of hair growth. Following ablation of the dermal papilla, resting hair follicles do not reenter the hair cycle (Rompolas *et al.*, 2012). Thus, a crosstalk between the dermal papilla cells and epithelial stem cells of the bulge and hair germ is necessary for subsequent cycling. The dermal papilla secretes FGF7, FGF10, and the BMP inhibitor, Noggin, all of which activate the bulge and hair germ stem cells to initiate the formation of a new hair shaft (Greco *et al.*, 2009; Oshimori and Fuchs, 2012). The hair follicle also communicates with subcutaneous adipose tissue and dermal fibroblasts during all stages of growth cycles. Mature adipocytes and dermal fibroblasts secrete BMP2 and BMP4, respectively, which help maintain quiescence of the hair follicle stem cells during the resting phase of the hair cycle (Plikus *et al.*, 2008). These adipose and dermal fibroblasts secrete BMPs to form a signaling field that affects large groups (units) of hair follicles. This field maintains and synchronizes the resting phase of each unit followed by the growth phase due to decreased secretion of BMP factors (Plikus *et al.*, 2008, 2009). The immature adipocytes can stimulate dermal papilla to secrete factors triggering activation of the hair germ stem cells. Specifically, the immature adipocytes secrete mitogenic platelet-derived growth factor A (PDGFA) that binds its cognate receptor in the dermal papilla cells (Festa *et al.*, 2011); however, the downstream effectors of this signaling pathway in these cells are not yet elucidated. It is possible that other factors produced by intradermal adipocytes influence the dermal papilla or hair follicle stem cells, therefore, additional studies are needed to identify other potential signaling mechanisms (Park *et al.*, 2010).

In conclusion, the skin contains distinct sets of progenitor cells, almost all of which are derived from the bulge and, once formed, signal to each other to trigger hair growth and skin renewal as well as repair following injury. However, this tightly ordered anatomical arrangement is not typical of all tissues as addressed in the following sections, but nonetheless has served as a 'Rosetta Stone' for understanding how stem cells behave *in situ* and what signals control their behavior. One striking aspect of the skin is that while the bulge cell is the likely origin of most of the progenitor pools, there are multiple reservoirs of cells reflecting different functions (i.e., whether the hair is cycling normally or undergoing regeneration). The context of the cells is also of critical importance. For example, as outlined above, the dermal papilla cells normally play a specific role in signaling, however, if purified and then grafted into host

skin, they adopt alternate cell fates that likely reflect their mesodermal origin (Driskell *et al.*, 2009).

Skeletal Muscle

A Unique Tissue-Specific Progenitor Cell Amid Cellular Neighbors

Skeletal muscle is composed of post-mitotic multinucleated myofibers that constitute the minimal functional unit responsible for voluntary muscular contraction (Yin *et al.*, 2013). In mammals, these multinucleate fibers are incapable of further division and depend upon resident progenitor cells for repair. Mauro (1961) described a subset of cells in post-natal skeletal muscle that he called ‘satellite cells’ because of their localization underneath the basal lamina but outside, or ‘satellite’ to the myofiber plasma membrane (Figure 2). Subsequent work has largely supported the assertion that satellite cells are the key, if not unique, skeletal muscle progenitor. In addition to their anatomical location, adult satellite cells can be recognized by the *Pax7* (Sambasivan *et al.*, 2011) M-cadherin (Irintchev *et al.*, 1994) and $\alpha 7$ -integrin expression (Yin *et al.*, 2013). In response to injury, satellite cells become mitotically activated and initiate expression of *MyoD* (Relaix and Zammit, 2012; Yin *et al.*, 2013). As activated satellite cells expand, a subset will progress through the myogenic program and differentiate while others reenter a quiescent state to restore the satellite cell pool reflecting an asymmetric lineage decision (Kanisicak *et al.*, 2009). The myogenic program

includes a specific sequence of gene expression involving initial activation of *Myf5* and *MyoD*, which in turn activate the expression of terminal differentiation genes including myogenin leading to cell cycle exit (Shih *et al.*, 2008). Myogenin promotes expression of genes coding for myofiber structural and contractile proteins (Wright *et al.*, 1989). After exiting the cell cycle, myoblasts fuse together to generate multinucleated myofibers. During this process, a subset of cells transit from a *Pax7* + /*MyoD*- state to a *Pax7* + /*MyoD* + state and then back to a *Pax7* + /*MyoD*- state (Zammit *et al.*, 2006; Zammit, 2008; Yin *et al.*, 2013). Perhaps one of the most compelling observations that satellite cells are the unique myogenic resident progenitor comes from a series of studies that show that genetically mediated ablation of the satellite cell population in adult muscle leads to a complete loss of regenerative potential followed by fibrosis and ectopic fat formation (Murphy *et al.*, 2011; Sambasivan *et al.*, 2011). Unlike the hair follicle, which has multiple reservoirs of stem cells upon which to draw if the bulge compartment is completely lost, there does not appear to be a competent resident ‘primitive’ stem cell that can give rise to satellite cells.

The skeletal muscle stem cell niche is a complex environment in which cell-cell interactions are finely regulated to assure normal postnatal growth and regeneration. Physical interactions with the sarcolemma and the basal lamina regulate satellite cell quiescence (Ten Broek *et al.*, 2010; Yin *et al.*, 2013) and freshly isolated satellite cells will spontaneously reenter the cell cycle and activate the myogenic differentiation program (Musaro and Barberi, 2010). However, contact with the myofiber is not sufficient to drive quiescence suggesting

Figure 2 Schema depicting a cross-section of skeletal muscle fibers. Muscle fibers are multinucleated and comprise the bulk of muscle tissue mass. In between the fibers are vessels, and a variety of interstitial cells including adipogenic progenitors and fibroblasts. Immediately adjacent to the muscle fiber are the satellite cells that are muscle-lineage committed progenitors. As illustrated here, these cells all lie in close proximity allowing for cell-cell signaling that controls their stem cell behavior.

that other factors coming from the environment are needed (Beauchamp *et al.*, 2000; Keire *et al.*, 2013). Several paracrine soluble cytokines, chemokines, and other molecules released by the surrounding cells (myofibers, microvasculature, interstitial cells, neuromuscular junctions, and circulating or resident immune cells), as well as systemic factors maintain the quiescent state of satellite cells or promote their proliferation and differentiation (Brack *et al.*, 2007; Ten Broek *et al.*, 2010). While the satellite cell fulfills the key characteristics for a tissue-specific stem cell (i.e., they generate new muscle tissue and can self-renew), they display relatively poor engrafting potential in rescuing diseased muscle. Moreover, the endogenous satellite cells undergo exhaustion following many rounds of cell division in the context of degenerative muscle diseases (Conboy *et al.*, 2005; Brack and Rando, 2012; Pannerec *et al.*, 2012; Relaix and Zammit, 2012; Sousa-Victor *et al.*, 2014). While some evidence points to intrinsic changes that occur in satellite cells following repeated rounds of injury or chronic disease, it has been shown that a 'healthy' muscle environment is critical for proper satellite cell function and subsequent regeneration. Specifically, satellite cells are highly responsive to immediately adjacent cells including the muscle fiber, vessel associated cells and interstitial cells. Unlike the hair follicle, in which the stem cell niche consists of groups of closely associated progenitor populations in anatomically definable compartments (Figure 1), satellite cells are scattered throughout the muscle tissue, making the assignment of an anatomically definable niche less clear (Figure 2). However, as specific paracrine signaling events between the satellite cell and surrounding cell types are elucidated, a functional stem cell niche becomes apparent. In addition, myogenic capacity has been found in non-satellite cells resident in skeletal muscle (Dellavalle *et al.*, 2007, 2011; Mitchell *et al.*, 2010; Pannerec *et al.*, 2013). However a role for these cells remains unclear, particularly in light of the observation that genetic ablation of the satellite cell population specifically is sufficient to severely abrogate regenerative capacity. As we will see below, similar results are obtained when other interstitial populations are ablated, suggesting that multiple cellular components are required for proper regeneration.

In 2010, two independent reports described the isolation of an adult skeletal muscle resident cell population with adipogenic potential (Joe *et al.*, 2010; Uezumi *et al.*, 2010). This cell population, referred to most commonly as fibroadipogenic progenitors (FAPs), can be readily isolated due to the expression of Sca-1 and PDGFR α (Joe *et al.*, 2010) and identified in the interstitial space between the muscle fibers (Figure 2). Further analyses showed the existence of a common Sca-1⁺/PDGFR α ⁺ progenitor cell type responsible for adipose tissue as well as fibrosis deposition (Uezumi *et al.*, 2011). These progenitor cells do not express Pax7, α 7-integrin, or other satellite cells markers nor do they undergo myogenic differentiation under normal conditions (Joe *et al.*, 2010; Uezumi *et al.*, 2010). While skeletal muscle tissue contains both fibrotic (connective) and adipose components, chronic degenerative myopathies lead to a loss of myogenic regeneration coupled with an increase in fibrotic and fat deposition suggesting that a critical balance is maintained between these closely associated cell types. Coculture experiments have shown that FAPs exert a promyogenic effect on activated satellite cells (Joe *et al.*, 2010; Uezumi *et al.*, 2010,

2011). Using genetically mediated cell ablation models, it has been shown that in the absence of FAPs, skeletal muscle undergoes poor regeneration (Murphy *et al.*, 2011) and can trigger muscle wasting (Roberts *et al.*, 2013) underlining an important role for FAPs as essential for proper muscle regeneration and homeostasis.

Like all tissues, skeletal muscle is vascularized and in addition to the critical role of supplying blood, the vessels contain specific cell types that have progenitor properties. Pericytes are localized around small vessels in all tissues and can be identified through specific markers such as alkaline phosphatase (ALP), neuronal-glial antigen 2 chondroitin sulfate proteoglycan (NG2), cluster of differentiation-146 (CD146), and platelet-derived growth factor receptor beta (PDGFR β) (De Angelis *et al.*, 1999; Dellavalle *et al.*, 2007; Tonlorenzi *et al.*, 2007). Pericytes will proliferate *in vitro* and will differentiate into several mesodermal lineages including osteoblasts, chondroblasts, adipocytes, smooth, skeletal, and cardiac muscle cells (Doherty *et al.*, 1998; De Angelis *et al.*, 1999; Farrington-Rock *et al.*, 2004; Dellavalle *et al.*, 2007; Tonlorenzi *et al.*, 2007; Barbuti *et al.*, 2010) suggesting a high degree of cell fate plasticity. In skeletal muscle, two subpopulations of NG2⁺ pericytes have been recently described, one with myogenic capacity (PDGFR α ⁺Nestin⁻) and one with adipogenic capacity (PDGFR α ⁺Nestin⁺) (Birbrair *et al.*, 2013). While the discovery of FAPs provides clear evidence that local progenitors with distinct cell fates communicate with each other to execute proper stem cell function, there is also evidence that invading immune cells provide important clues to properly coordinate stem cell function. Immune cells are the 'first responders' following muscle injury. Injured muscle is infiltrated by monocytes and leukocytes to support resident macrophages in clearing by microbes, dead cells, and debris (Elhelu, 1983). Macrophages become activated in response to injury and these activated, or 'M1,' macrophages convert to M2 macrophages and secrete anti-inflammatory factors (Bosurgi *et al.*, 2012). Blocking the conversion of M1 to M2 macrophages blocks proper muscle regeneration including proper revascularization (Tidball and Wehling-Henricks, 2007; Wang *et al.*, 2014).

In conclusion, even though the 'stem cell' niche does not overtly show the degree of compartmentalization and topological organization that we saw in the skin, there is nonetheless a complex and important balance between the resident progenitors as well as circulating cells that come together to control the stem cell niche and its functionality. What distinguishes the skin from skeletal muscle in this regard, is the fact that these progenitor cells may well remain quiescent throughout the lifetime of the organism and do not carry out a regular cycling or 'renewal' process, but remain relatively potent throughout life, except in response to chronic disease and aging.

The Adult Central Nervous System Stem Cell Niche

A Tissue with Functional Stem Cells but Poor Regenerative Capacity

The mammalian central nervous system (CNS: brain and spinal cord) is essentially incapable of any significant regeneration in response to injury due to trauma or stroke.

Specifically, damaged neurons are not replaced and, instead, changes in neural connectivity and processing occur as the major response to brain or spinal cord injury. This stated, restricted regions of the brain do undergo neuronal turnover and the CNS possesses several populations of bona fide neuronal stem cells that give rise to all CNS cell types *in vitro* including neurons, oligodendrocytes, and astrocytes. Unlike the skin and

skeletal muscle that display pronounced regenerative capacity, the apparent inability of the CNS to regenerate originally led to the general consensus that the CNS does not contain stem cells, a view that has reversed in the last decade. As such, the field of the adult CNS stem cell niche is relatively new, and progress in this field, while rapid, lags behind that of many other tissues. Whether new knowledge in this emerging field will ultimately lead to new therapies to treat brain and spinal injuries is unclear, but this promise is one main driver in the field.

Two distinct neural stem cell niches have been identified in the CNS of adult rodents: the ventricular-subventricular zone (SVZ) next to the lateral ventricles and the subgranular zone (SGZ) in the hippocampus (Doetsch *et al.*, 1999; Seri *et al.*, 2001). Both niches have different structures and functions. During homeostasis, neuroblasts are continuously produced in the SVZ and subsequently migrate in chains through the rostral migratory stream (Figure 3; Doetsch and Alvarez-Buylla, 1996). They differentiate into olfactory interneurons once they reach the olfactory bulb. In the dentate gyrus, the SGZ neural stem cells generate granule cells (Figure 4). These newly generated neurons contribute to spatial memory, learning, and more specifically to pattern separation function, a characteristic not shared by the neighboring fully mature granule cells (Lacar *et al.*, 2014). Rare scattered progenitor cells are also found throughout the brain parenchyma, outside the two neurogenic niches described in this article.

Figure 3 The ventricular-subventricular zone neural stem cell niche (SVZ). A, neuroblast; astrocyte; B1, neural stem cell; BV, blood vessel; C, transit amplifying cell; E, ependymal cell; M, ramified microglia; P, pericyte; RMS, rostral migratory stream; SVZ, subventricular zone; V, lateral ventricle; VZ, ventricular zone. Double arrow: neuronal projections of non-neurogenic regions such as raphe nuclei, substantia nigra, ventral tegmental area, and striatum. A linear orange process bridging blood vessel and ependymal cells represents Fractones.

The V-SVZ Neural Stem Cell Niche

The adult neural stem cell of the SVZ is referred to as the B1 cell (Figure 3). Each B1 cell spans three domains (Fuentelba

Figure 4 The subgranular zone (SGZ) neural stem cell niche. A, astrocyte; BV, blood vessel; CA3, cornu amonis 3; DG, dentate gyrus; GC, granule cell; GCL, granule cell layer; I, inhibitory interneuron; IGC, immature granule cell; IPC, intermediate precursor cell; M, ramified microglia; ML, molecular layer; Mo, mossy cell; P, pericyte; RA, radial astrocyte; SGZ, subgranular zone. Double arrows: synaptic inputs from a non-neurogenic region such as entorhinal cortex.

et al., 2012). In the proximal/apical domain, B1 cells directly contact the cerebrospinal fluid (CSF) of the lateral ventricles by a single nonmotile primary cilium (Mirzadeh *et al.*, 2008; Shen *et al.*, 2008). This process is surrounded by multiciliated ependymal cells that line the ventricular walls (Mirzadeh *et al.*, 2008). The intermediate domain contains the B1 cell body as well as B1 cell progeny, including the transit amplifying cells and neuroblasts. Microglia, the resident immune cells specific to the CNS, are also present throughout the CNS and associated with the SVZ. Finally, the distal domain links the B1 cell with the vasculature (Shen *et al.*, 2008). The blood–brain barrier is composed of endothelial cells, pericytes, and astrocytes end feet. Surprisingly, the blood–brain barrier appears to be leaky where clusters of B1 and transit amplifying cells are found (Tavazoie *et al.*, 2008). This punctual lack of glial end feet and pericyte coverage is a feature unique to the SVZ. Of note, like B1 cells, fractones bridge apical to distal domains with a close contact with each SVZ cell. These laminin-rich structures containing heparan sulfate proteoglycans are part of the niche extracellular matrix (ECM) (Mercier *et al.*, 2002).

The SGZ Neural Stem Cell Niche

This second neural stem cell niche is distinguished from the SVZ by its location and organization. The neural stem cells of the SGZ, called radial astrocytes (RAs), are present in the dentate gyrus of the hippocampus. The RAs are highly polarized and span three domains (Figure 4). The proximal domain, facing the hippocampal hilus, contains the RA primary cilium, blood vessels and is in direct contact with RAs, and to some extent hilar mossy cells and interneurons. Compared to the SVZ, angiogenesis is highly active in this domain with intense vascular remodeling (Palmer *et al.*, 2000). In the intermediate domain of the dentate gyrus, RAs extend long processes that contact other neural stem cells (Fuentelba *et al.*, 2012). RAs also possess small horizontal processes that may allow interactions with the neighboring cells. In fact, each RA cell body and its long shaft are surrounded by their differentiated progeny.

One RA successively generates intermediate progenitors type 1 and 2 (IPC), which are often found next to RA cell bodies (Kempermann *et al.*, 2003). These IPCs give rise to immature granule cells (IGC) that differentiate into fully mature granule cells. In contrast to the SVZ, newly born neurons do not migrate away from their niche and instead they reside in the dentate gyrus. Even if B1 cells and RA are found in a different microenvironment and generate different types of neurons, they do share key features. Both progenitors have ultrastructural characteristics of astrocytes with long processes. They express astroglial markers such as the glial fibrillary acidic protein (GFAP) and are found in close vicinity with the vasculature. Thus, as seen in the skin and skeletal muscle, the niche provides a microenvironment that permits multiple cell interactions.

Interactions between Niche Cells and Tissue Progenitors-Soluble Factors

A balance between proliferation and the number of differentiated cells generated is orchestrated by several mechanisms at

specific sites within the niche. Although a single signaling pathway is not restricted to one particular domain, some of the mechanisms involved in this adult neurogenic balance in each CNS niche are outlined below.

SVZ Interactions

The cerebrospinal fluid (CSF) contains multiple soluble factors such as the TGFs, IGFs, BMPs, Wnts, SHH, Slits, PDGFs, and retinoic acid (Redzic *et al.*, 2005; Lehtinen *et al.*, 2011). The main source of CSF production is the choroid plexus and the CSF composition reflects the physiological state of the animal (Redzic *et al.*, 2005). Importantly, even if B1 primary cilium is thought to integrate CSF soluble factors, highly concentrated growth factors within the lateral ventricles are able to penetrate the ependymal wall and bind to fractones (Kerever *et al.*, 2007). According to their position and local levels of EGFs, FGFs, and BMPs (i.e., BMP7) fractones can deliver growth factors to the niche cells (Mercier *et al.*, 2002). For example, neural progenitor cells express EGF receptor (EGFR) important for their proliferation (Doetsch *et al.*, 2002). Soluble factors can also originate from ependymal cells, SVZ cells, afferent axons, and systemic signals. Ependymal cells secrete noggin, a BMP antagonist, leading to SVZ progenitor proliferation and an increase in neuroblast generation (Lim *et al.*, 2000). Additionally, ependymal cells express the receptor LRP2 that confines BMP4 inducing proliferation of B1 cells (Gajera *et al.*, 2010). As with other stem cells, the maintenance of the neural stem cell pool involves a balance between proliferation, quiescence, differentiation, and self-renewal. One pathway underlying this in the SVZ is the canonical Notch signaling pathway (Imayoshi *et al.*, 2010). Notch ligands are expressed within the whole SVZ niche. As an example, transit amplifying cells express ASCL1, also known as MASH1, which increases the expression of Notch ligands that in turn inhibits B1 cell proliferation. The downstream effector of Notch HES1 transcriptionally represses ASCL1. As a second example for Notch signaling, niche astrocytes secrete Dlk1 that binds to neural stem cells in order to maintain quiescence in a dose-dependent manner (Feron *et al.*, 2011).

CNS activity is also involved in regulating the stem cell niche. For example, newly born neuroblasts spontaneously release the neurotransmitter, gamma-aminobutyric acid (GABA) (Liu *et al.*, 2005). Both transit amplifying cells and B1 cell possess GABA receptors that leads to an inhibition of cell cycle progression. This inhibition of neurogenesis is due to an epigenetic mechanism via phosphorylation of H2AX, a marker of DNA-damage (Fernando *et al.*, 2011). To compensate, B1 and transit amplifying cells secrete the diazepam binding inhibitor (DBI) into the ECM that competes with GABA for its receptors (Alfonso *et al.*, 2012). The microglia also participate in regulating the niche via the secretion of TGF- α and BDNF that enhance proliferation and neural differentiation (Walton *et al.*, 2006). As we saw in the skin stem cells, the position of the neural stem cell within the niche is critical. Endothelial cells interact closely with progenitor cells. Both ependymal cells and endothelial cells secrete the chemokine SDF1 (Kokovay *et al.*, 2010). Since endothelial cells produce higher levels of SDF1, a gradient is established along the niche.

Thus activated B1 and transit amplifying cells migrate toward the blood vessel and adhere via $\alpha 6\beta 1$ -integrin expression. Disrupting this vascular adhesion leads to proliferation defects *in vivo* (Kokovay *et al.*, 2010). Additionally, endothelial cells secrete betacellulin, an EGF-like growth factor, that induces proliferation and subsequent neurogenesis (Gomez-Gavira *et al.*, 2012). Non-neurogenic regions can also influence the neural stem cell niche. For example, dopamine is released by neuronal projections of the substantia nigra and the ventral tegmental area. This input gives rise to an increased proliferation of transit amplifying cells (Silva-Vargas *et al.*, 2013).

SGZ Interactions

Vascular secreted factors such as IGF1, brain-derived neurotrophic factor (BDNF), and VEGF promote progenitor proliferation and differentiation (Cao *et al.*, 2004; Chen *et al.*, 2005; Llorens-Martin *et al.*, 2009). As in the SVZ, canonical Notch signaling is active in the dentate gyrus neurogenic niche. Radial astrocytes express the downstream effectors of Notch HES5 and RBPJ κ , which directly binds to the Sox2 promoter and activates its transcription leading to RA quiescence (Ehm *et al.*, 2010). SOX2 signaling then inhibits neuronal fate determinant NeuroD (Kuwabara *et al.*, 2009). Nonetheless granule cells, hilar cells, and RA, as a cell-autonomous regulation, express noggin (Bonaguidi *et al.*, 2008). Thus multiple signaling pathways acting in both paracrine and autocrine fashion control the SGZ.

A Role for the CNS Stem Cell Niches

What purpose does neurogenesis serve in the brain if concentrated into small niches that do not renew neurons throughout the brain? Some evidence points to specific roles in controlling learning, memory, and basic capacities to integrate information in a process referred to as pattern separation. For example, newly born granule cells at 3–4 weeks of age are particularly different in terms of function from the fully mature ones. These young granule cells possess a unique circuitry and physiology for a limited period of time and play a dedicated role in pattern separation (Nakashiba *et al.*, 2012). In the SGZ, as seen in the SVZ, neurotransmitters play a critical role in this process. GABA, synthesized by parvalbumin interneurons, induces depolarization of IPCs toward a neuronal differentiation. At 1–2 weeks of age, they receive synaptic GABAergic inputs. The following week they start to express glutamatergic receptors and become hyperpolarized. At 4 weeks of age, they receive glutamatergic inputs from the entorhinal cortex and undergo less inhibitory inputs from the interneurons as compared to mature cells. At this stage, the young granule cells are hyperexcitable (Marin-Burgin *et al.*, 2012). Finally, around 6–8 weeks of age, granule cells are fully mature and inhibition becomes dominant.

The position of radial astrocytes in the entire dentate gyrus, from the most studied septal to temporal, may also influence their fate and function due to inputs from different brain areas. The SVZ serves to generate diverse subtypes of olfactory neurons that are specifically derived from SVZ microdomains (Merkle *et al.*, 2007). The olfactory lobe is continually supplied

with new neurons making it a rather unique exception to most other brain regions. Thus, both the SVZ and the SGZ serve very specific roles and brain functions rather than act as a reservoir for the entire brain. This suggests that perhaps the rest of the CNS does not have ‘access’ to a progenitor pool of cells. However, as outlined below, other progenitor cells have been found outside of the SVZ and SGZ that may serve this purpose, albeit, with a more limited cell fate potential such as glia.

Stem Cell Potential Outside the Neurogenic Niches

NG2 glia

NG2 glia is a specific glia cell type that is scattered in the brain parenchyma. Almost all of these cells are NG2⁺PDGFR α ⁺ and undergo a slow rate of division, more than once a month, to self-renew and produce myelinating oligodendrocytes (Dimou *et al.*, 2008; Rivers *et al.*, 2008; Psachoulia *et al.*, 2009). These represent a very limited progenitor cell type that renews the supporting glia cells but does not contribute to neurons.

Reactive Astrocytes

Astrocytes are the support cells of the CNS. Among other functions, they modulate neuronal synapses and vasculature. Even though they share expression signatures with neural stem cells, astrocytes do not divide under normal conditions. However, following brain injury such as ischemic stroke, astrocytes near the lesion undergo astrogliosis after several days. This process is characterized by a pronounced change in morphology and gene expression that leads to reactive astrocyte proliferation and acquisition of neural stem cell properties (Buffo *et al.*, 2008). This astrocytic response has both beneficial and detrimental impact on tissue repair. Notably, the astrocytes produce a scar to protect the tissue surrounding the lesion from receiving additional inflammatory signals. However, later the scar inhibits axonal regeneration and neurogenesis (Pekny and Pekna, 2004; Sofroniew and Vinters, 2010). While many of the signals released upon brain injury overlap with those found in the neural stem cell, the astrocytes are not capable of forming multiple cell types such as the progenitors found in the SVZ and SGZ (Buffo *et al.*, 2008).

In conclusion, while there are specific niches with multipotent stem cells, they appear to serve very specific functions for the brain where a more disperse population of cells exists with limited stem cell fate potential that appear to function primarily in response to injury in order to limit the extent of injury and effect a repair that is more like scar formation in other tissues. Whether these progenitor cells can be manipulated to effect more substantial repair in the brain or spinal cord will await future research in this field.

The Heart-Evidence for a Cardiac Stem Cell Niche?

Thus far, we have examined two tissues with pronounced regenerative capacity: skin that regenerates continually as well as in response to injury and skeletal muscle, which regenerates only in response to injury. In addition, we have examined the

CNS, which has little regenerative capacity but nonetheless possesses bona fide stem/progenitor cells that serve very specific roles and regions in the brain. We now look at the adult mammalian heart that is essentially incapable of any recognizable regeneration (Laflamme and Murry, 2011; Kikuchi and Poss, 2012; Xin *et al.*, 2013). At the time of writing this article, the question of whether or not the heart has stem cells capable of generating new cardiac tissue *in vivo*, in particular, new cardiac muscle, remains unresolved. As such, we can witness a field that is emerging and how different studies begin to form a picture of cardiac stem cells and their potential contribution to cardiac regeneration. As degenerative cardiac diseases are a major cause of mortality in developed countries, the field of cardiac stem cell biology has significant importance for the clinic and presents a major challenge to basic research in stem cells.

Unlike the skin and skeletal muscle, cardiac injury leads invariably to fibrosis and scar tissue formation without any significant restoration of lost cardiac muscle tissue. This suggests that the heart is devoid of progenitor cells. However, recent studies have shown robust cardiac regeneration following injury in newborn mice, although this regenerative capacity is lost by the first week of life (Porrello *et al.*, 2011; Haubner *et al.*, 2012). This raises the possibility that a transient population of progenitor cells is present in the heart just after birth. In addition, while the ability of the adult heart to regenerate in response to a large injury is absent, myocardial recovery has been reported in adult mouse hearts following drug-induced myocardial damage that is diffuse and affects cardiac muscle cells scattered throughout the heart (Ellison *et al.*, 2013). However, these findings are disputed as their conclusions are dependent upon lineage tracing mouse models that may not be as reliable as initially believed (Hesse *et al.*, 2014; Nadal-Ginard *et al.*, 2014; van Berlo *et al.*, 2014). At present, no consensus exists regarding the cellular identity of cardiac progenitors in the heart, much less the mechanisms underlying cardiac recovery from injury. It is possible that the assumption that regeneration requires the presence of a resident population of stem cells is incorrect in the case of the heart. Indeed, some species of fish and amphibians can regenerate damaged myocardium through a mechanism of cardiomyocyte dedifferentiation and proliferation and based on the available data, it appears that the neonatal mammalian heart undergoes a similar process of cardiac muscle dedifferentiation (Flink, 2002; Poss *et al.*, 2002; Hsieh *et al.*, 2007; Kuhn *et al.*, 2007; Drenckhahn *et al.*, 2008; Bersell *et al.*, 2009; Porrello *et al.*, 2011; Witman *et al.*, 2011; Haubner *et al.*, 2012). However, several reports demonstrated that endogenous cardiac stem cells (eCSCs) may contribute to the replacement of mouse cardiomyocytes during normal aging and following injury (Poss *et al.*, 2002; Beltrami *et al.*, 2003; Oh *et al.*, 2003; Hsieh *et al.*, 2007; Jesty *et al.*, 2012; Ellison *et al.*, 2013; Uchida *et al.*, 2013).

Cardiac Stem Cell Niches

If cardiac stem cells exist, where are they found and do they resemble other more characterized stem cell niches in tissues such as the skin, skeletal muscle, or CNS? Potential eCSCs

have been identified by their expression of different membrane markers (c-Kit, SCA-1, PDGFR α , MDR-1) and transcription factors (Islet-1, NKX2.5, GATA4) (Beltrami *et al.*, 2003; Oh *et al.*, 2003; Oyama *et al.*, 2007; Tallini *et al.*, 2009; Chong *et al.*, 2011, 2013; Unno *et al.*, 2012; Uchida *et al.*, 2013). While these markers have been used to purify cells for study *in vitro* and subsequent engraftment, they have also been used to identify these cells *in vivo*. These studies reveal that eCSCs are located in two 'domains': one domain is dispersed throughout the interstitial space between the cardiac muscle cells and the other domain consists of a cell layer surrounding the heart referred to as the epicardium.

Cardiac interstitial niches are located between cardiomyocyte fibers and represent randomly oriented ellipsoid structures that harbor heterogeneous, non-muscle cells, including eCSCs, lineage-committed cells (LCCs), and cardiac fibroblasts (Urbanek *et al.*, 2006; Ruiz-Villalba *et al.*, 2013). eCSCs can be identified by specific cell-surface marker (c-Kit, SCA-1, or MDR-1) but do not express cardiac cell lineage proteins and hematopoietic markers (Urbanek *et al.*, 2005). LCCs consist of progenitors expressing both eCSC markers and a lineage-specific transcription factor characteristic for cardiomyocytes, endothelium, or smooth muscle precursors (Urbanek *et al.*, 2006). Cardiac interstitial cells, including stem cells, are located throughout the heart with a much higher concentration at the apex and atria of the heart.

In addition to cardiac interstitial stem cells, progenitor cells have been identified in the ventricular epicardial and sub-epicardial regions of the heart initially based on their hypoxic environment (Kocabas *et al.*, 2012). The epicardium represents an epithelial layer on the surface of the heart adjacent to the myocardium (Schlueter and Brand, 2012). The subepicardial region encompasses the outermost three cell layers of the myocardium (Kocabas *et al.*, 2012). These areas are characterized by the lowest capillary density in the ventricle and expression of hypoxia-inducible factor 1 α (Hif1 α) (Kocabas *et al.*, 2012). Ventricular epicardial-subepicardial niche harbors so-called 'glycolytic cardiac progenitors' that resist hypoxic stress and utilize anaerobic glycolytic metabolism, rather than the oxygen-dependent mitochondrial oxidative phosphorylation. These cells do not express eCSC (c-Kit or SCA-1), endothelial, or hematopoietic markers, but do express cardiac progenitor and epicardial markers (NKX2.5, GATA4, WT1, and TBX18). Glycolytic cardiac progenitors are self-renewing and capable of differentiating into three cardiac lineages (cardiomyocytes, endothelial, and smooth muscle cells) *in vitro* (Kocabas *et al.*, 2012).

Interactions between Niche Cells and the Tissue Progenitors

Cell-cell Interactions

eCSCs are connected structurally and functionally with each other and the supporting cells by junctional and adhesion proteins – connexins and cadherins (Urbanek *et al.*, 2006). Connexins are gap junction proteins that allow direct inter-cellular communication by passage of small molecules and electrical impulses (Sohl and Willecke, 2004). Cadherins are components of adherens junctions that mediate Ca²⁺-dependent cell-cell adherence and stem cell behavior within

the niche: maintenance, proliferation, and migration (Marthiens *et al.*, 2010). N- and E-cadherin bind eCSCs and LCCs with each other and surrounding cardiomyocytes and fibroblasts, whereas Connexin 43 and 45 form gap junctions between these cells in the cardiac interstitial niches (Urbanek *et al.*, 2006).

Cell-Matrix Contacts

ECM provides structural, mechanical, and biochemical environment of the niche and influences stem cell fate; the major ECM components include laminins and fibronectins (Brizzi *et al.*, 2012; Gattazzo *et al.*, 2014). Interaction between the ECM and stem cells is mediated by a number of cell receptors, including integrins (Gattazzo *et al.*, 2014). Cardiac interstitial niches are characterized by the presence of laminin-8/9 and laminin-10/11, which are also distributed throughout the myocardium. β 1-integrin is present on the surface of both eCSCs and LCCs. However, co-localization of α 2-chain of laminin and fibronectin with α 4-Integrin is restricted only to the eCSCs and suggests a role in the preservation of the undifferentiated state of the eCSCs (Urbanek *et al.*, 2006).

Juxtacrine and Paracrine Signaling

The niche provides the paracrine (targeting cells in vicinity) and juxtacrine (targeting adjacent cells) signaling that regulates the fate of resident stem cells. The epicardium regulates myocardial growth and coronary development through secretion of paracrine factors in both fetal and injured adult mouse hearts (Lavine *et al.*, 2005, 2006; Zhou *et al.*, 2011). A number of epicardium-secreted factors have been identified in the adult injured heart including vascular endothelial growth factor A, stromal cell-derived factor 1, and members of fibroblast growth factor signaling (Zhou *et al.*, 2011). However, the effect of the epicardial paracrine signaling on eCSCs has not been described yet. Notch signaling has been shown to regulate eCSC fate in the cardiac interstitial niches. c-Kit-positive eCSCs express Notch1, whereas the adjacent, supporting cells in the niche express the Notch ligand Jagged1, a membrane-bound protein (Boni *et al.*, 2008). Activation of Notch1 results in up-regulation of NKX2.5 expression, favors the commitment of eCSCs to cardiomyocyte fate, and promotes cardiomyocyte formation (Boni *et al.*, 2008; Urbanek *et al.*, 2010). Pharmacological inhibition of Notch pathway in newborn mice results in more than 50% decrease in cardiomyocyte number and leads to development of dilated myopathy (Urbanek *et al.*, 2010). Levels of Notch1 expression decrease in adult myocardium compared to the neonatal tissue, but rise in response to acute infarction. Overexpression of Notch1 after cardiac injury promotes cardiomyocyte survival but it is unclear if stem cells are directed to a muscle cell fate in the adult (Gude *et al.*, 2008).

The epicardium is the only cardiac layer that originates outside of the primitive heart tube – from an extracardiac primordium, known as proepicardial organ. This structure exists between days 9 and 11 of embryonic development in mice. The proepicardial organ gives rise to the cell aggregates that float through the pericardial cavity, attach to the

myocardium, and fuse to form an epithelial layer around the heart (Manner *et al.*, 2001). Once established, embryonic epicardial cells, marked by expression of WT1 and TBX18, undergo an epithelial–mesenchymal transition and contribute to cardiac fibroblasts, coronary smooth muscle cells, and cardiomyocytes (Cai *et al.*, 2008; Zhou *et al.*, 2008; Christoffels *et al.*, 2009). Epicardial cells from adult mouse heart lose this capacity and remain quiescent (Zhou *et al.*, 2011). However, in response to injury, the epicardium thickens, starts expressing fetal epicardial genes (*Wt1*, *Tbx1*, and *Raldh2*), and contributes to the formation of smooth muscle cells, fibroblasts, but not cardiomyocytes (Zhou *et al.*, 2011). Adult epicardium can be stimulated to give rise to cardiomyocytes after pretreatment of the heart with thymosin β 4, which reactivates WT1 expression and also restores vascular potential of the epicardium-derived progenitors (Smart *et al.*, 2007, 2011). A population of epicardial-derived cells with colony-forming ability can be isolated based on the expression of SCA-1 and PDGFR α from adult mouse hearts. Cardiac colony-forming cells are multipotent and can give rise to cardiomyocytes, endothelial and smooth muscle cells, adipocytes, cartilage, and bone when stimulated *in vitro* (Chong *et al.*, 2011). These cells are distinct from the c-Kit-positive eCSCs and do not arise from NKX2.5-positive cardiac progenitors (Chong *et al.*, 2011).

Fibroblasts present in the interstitial niches represent a highly heterogeneous cell population that remains poorly characterized. Several markers for these cells have been described, including Vimentin, FSP1, and DDR1; however, these markers lack specificity and identify only a subpopulation of cardiac fibroblasts (Zeisberg and Kalluri, 2010). A major developmental source of the cardiac fibroblasts is the proepicardial organ, but multiple other origins have been proposed including the bone marrow, embryonic stromal cells, pericytes, and endothelium (Norris *et al.*, 2008; Krenning *et al.*, 2010; Zeisberg and Kalluri, 2010). Interestingly, embryonic and adult cardiac fibroblasts exhibit different properties. For example, embryonic cardiac fibroblasts stimulate proliferation of the cardiomyocytes, whereas adult cardiac fibroblasts induce cardiomyocyte hypertrophy (Ieda *et al.*, 2009). Cardiac fibroblasts play a major role in cardiac fibrosis characterized by excess deposition of ECM (Krenning *et al.*, 2010). Fibrosis occurs and persists in response to cardiac injury in adult hearts. However, in newborn mouse hearts, some scarring also appears after injury, but it resolves after three weeks (Porrello *et al.*, 2011; Haubner *et al.*, 2012).

While the findings summarized above support the existence of cardiac stem cells, our current knowledge of the biology of eCSC niches remains limited. The heterogeneity of eCSCs and their different properties further complicate the research of the niches. Although several studies have tried to address this issue, still little is known about eCSC niches: their architecture, distribution in the heart, interaction with the eCSCs, developmental origins, as well as changes during aging and different pathologies. The heterogeneous nature of cardiac fibroblasts that constitute the niche and the lack of specific markers hinder our understanding of their function. The crosstalk between eCSCs and adjacent cardiomyocytes also has not been addressed. Finally, considering multiple reports of cardiac regeneration due to cardiomyocyte dedifferentiation and proliferation, without participation of eCSCs, it is tempting to

suggest that cardiac niches may also play role in this process but do not directly give rise to new cardiac muscle. Instead, resident progenitors in the heart, particularly in the epicardium, may be an important source of vascular progenitors that are essential in reperfusing the heart following injury. It is well established that a quick revascularization of damaged heart tissue limits the extent of permanent injury to the heart. Future studies should provide answers to these questions.

Overall Conclusions and Future Directions

In this article, we have examined four tissue types, each representing a different challenge for stem cell biology and regenerative medicine. The skin, specifically the hair follicle, is a tissue that continually self-renews and displays a remarkable capacity to regenerate following injury. Other examples of highly regenerative and constitutively cycling tissues include the blood (bone marrow) and intestine. It is therefore no surprise that progenitor cells in these tissues are well characterized and cellular and molecular events underlying tissue homeostasis and regeneration have been described in detail. Still, these tissues hold challenges for regenerative biology. Specifically, all these tissues show a decline in regenerative capacity with age and even in the absence of damage, tissue integrity declines with age. Why this occurs is less understood. These tissues are also a sight for malignancies, some of which may be a result of stem cells that undergo transformation into precancerous and cancerous cells. Indeed, their high stem cell competence may present a higher risk of cancer. In skin, the niche is tightly organized such that the various progenitors are situated in a precise and discreet location that governs their exposure to mitogens, morphogens, and other cellular neighbors that is critical to proper function. In the case of skeletal muscle, the niche appears less highly organized – a feature that likely reflects the requirement of stem cells scattered throughout the tissue to affect repair in regions that are injured due to exercise or major physical damage. Still, as seen in the skin, there is an association of the progenitors with muscle fibers, blood vessels, and interstitial cells that are themselves progenitors (contributing to fat and fibrosis) that appear to play a role in governing stem cell competence. In skeletal muscle, there is no evidence that progenitors cycle or are recruited on a regular basis, however like in the skin, the progenitors are recruited in response to injury. In the case of the CNS, several populations of progenitors have been identified, however they do not appear to play a significant role in regeneration despite their capacity to form all the essential cell types in the CNS including neurons. It would appear that the CNS, at least in mammals, is not programmed to regenerate – a limitation that may reflect functional requirements for the brain to retain memory and learning, however, this is more speculation than fact. Nonetheless, it is possible that researchers can tap into the stem cell potential, specifically by harnessing the signals that govern the stem cell niches in the CNS to affect regeneration, at least in the spinal cord for which there is a critical need. Lastly, we examined the heart. Like many tissues in the body, the identity of resident stem cells is a work-in-progress. Clearly cells can be identified that generate blood vessels and connective tissue, but stem cells that lead to

new cardiac muscle *in vivo* appear to either exist, but not function at high capacity, or be an artifact of tissue culture techniques. Whether these cells offer any therapeutic value will be of keen interest in the coming decade. As in all tissues covered here, understanding the signals that govern cardiac progenitors in their niche will prove invaluable to the development of therapeutic approaches. The transient capacity of cardiac muscle cells to dedifferentiate may also prove to be an essential tool in the future. The stem cell field is still young and our view of stem cells in adult tissues, and how to ultimately harness them in the context of regenerative medicine remains promising for the next generation of researchers.

Acknowledgments

This work comes from the Stem Cell and Regenerative Medicine Research Team that is part of the UMRS 1166 (ICAN) research unit. The team and members are supported by the European Community Seventh Framework Program project ENDOSTEM (Activation of vasculature associated stem cells and muscle stem cells for the repair and maintenance of muscle tissue-agreement number 241440) and the ITN program INGENIUM. We are also supported by ANR 'Laboratoire d'Excellence' program REVIVE and the IHU-ICAN projects and EPISTEM.

Cancer Stem Cells

Definitions and History

Stem cells are defined as cells that possess the cardinal features of multipotentiality, self-renewal, clonogenicity, and proliferation. It was originally proposed in the 1930s that within some tumors there exists a similar small subpopulation of tumor cells that is capable of regenerating the phenotypic heterogeneity of the original tumor in its entirety also displaying the four defining features of regular stem cells. This description has since become known as the cancer stem cell hypothesis. The early data that led to the cancer stem cell hypothesis being developed were based on the mouse models of leukemia (Furth, 1937). Prior to this it had been assumed that in order to transmit a malignancy from one animal to another many thousands of cells were required for transplantation. Furth hypothesized that these data were consequent on the genetic background of the mouse and that a more inbred mouse may require less cells to be transplanted. Using young inbred mice reestablishment of the original parental tumor from just a single cell was demonstrated. Interestingly, Furth also reported that not every injection of a single cell was successful concluding, somewhat prophetically, "It may be supposed, furthermore, that not all cells are capable of reproduction and that cells which do not reach an organ favorable for their growth perish."

It wasn't however until the work of Dominique Bonnet and John Dick in the 1990s that the cancer stem cell hypothesis was formally proven. In their seminal publication these authors demonstrated that fluorescence-activated cell sorting (FACS) of leukemic cells with antibodies that recognized the cell surface antigens CD34 and CD38 enriched for a population that could initiate leukemic proliferation when injected in immune compromised NOD/SCID (non-obese diabetic with severe combined immunodeficiency disease) mice (Bonnet and Dick, 1997). Using serial transplantation of tumors together with FACS analysis they were able to demonstrate that CD34⁺/CD38⁻ marked a population that contained the cancer stem cells of leukemia. Further, they also showed that a similar CD34⁺/CD38⁻ population appeared to also represent the cell-of-origin of leukemia. These early experiments paved the way for the identification of putative cancer stem cells in many other malignancies. Whilst xenotransplantation has historically formed a key assay in cancer stem cell biology, it is increasingly recognized that this approach has significant limitations and newer techniques are now being employed to validate historical xenotransplantation data.

Tumor Heterogeneity

It has become increasingly evident that in tumors resides both genetic heterogeneity and cellular functional heterogeneity. Traditionally there exists two descriptions explaining this heterogeneity; these have become known as the stochastic and

cancer stem cell models of tumor development. In the stochastic model the functional heterogeneity seen occurs as a result of random differentiation of an equipotent population of undifferentiated tumor cells. Layered on top of this stochastic differentiation exists clonal genetic evolution where distinct individual genetic clones may have the capacity for greater clonogenic potential. In the cancer stem cell model, however, there is a stricter hierarchical arrangement of cells within the tumor where only a certain subset (the cancer stem cells) retain capacity for self-renewal and proliferation. This latter explanation is more analogous to normal tissues where a structured hierarchical arrangement generally exists. Genetic clonal evolution theory can also be layered on top of the cancer stem cell model; each genetic clone possesses its own hierarchical organization with cancer stem cells at the apex. As clonal evolution develops and certain mutations are selected for, these new genetic clones can possess an increased number of cancer stem cells. Eventually, as tumor evolution continues a situation develops where almost all of the dominant genetic clone may essentially behave in a highly aggressive cancer stem cell-like manner (Figure 1).

Understanding and resolving functional and genetic heterogeneity in tumors to truly understand cancer stem cell biology will in the future require experiments that combine analysis of both of these facets concurrently. It is increasingly apparent that many of the conclusions made to date may be artefactual and assay dependent.

Terminology

Within the field the term 'cancer stem cell' is controversial and an alternative nomenclature – the tumor initiating cell (TIC) has also been used. The debate around this terminology has arisen for several reasons including the prevalence of the so-called cancer stem cells that have been found within some tumors, for example, in some melanomas they appear to make up the majority of the cells present within the tumor. Also impacting the use of the term cancer stem cell is the recently observed phenomenon of phenotypic plasticity within some tumor cell populations where it has been demonstrated that the stem state is not fixed and is both inducible and reversible. The question raised being is a cancer stem cell defined by being at that moment in time clonogenic or one that possesses that ability only in a context-dependent manner.

Recently the distinction between the terms cancer stem cell and TIC have been eloquently dissected (Kreso and Dick, 2014). Here a TIC is defined as a cell that is capable of tumor initiation through xenotransplantation, self-renewal being demonstrated by serial xenograft passage that also importantly generates daughter cells that may proliferate but are unable to reestablish the parental tumor on serial xenograft passage. A cancer stem cell is described as being distinct in that whilst possessing all the features of a TIC it can also be prospectively isolated.

Figure 1 Schematic representing cellular and genetic tumoral heterogeneity. Although originating from a founder mutated cell, three different genetic clones have evolved and are represented in the tumour by the green, red, and blue colored cells. Within each clone exist variable quantities of cancer stem cells (darker colored cells). Whilst the blue genetic clone contains very few cancer stem cells, plasticity in cell fate has developed where a noncancer stem cell has metastasized to a separate location with an alternative niche (yellow cells). Here the noncancer stem cell has undergone a change in fate to a cancer stem cell and an aggressive metastasis has developed made up in entirety of cancer stem cells.

Modes of Identification

Much of the debate around the existence of cancer stem cells has arisen as a result of the assays used to define cancer stemness. There are several *in vitro* assays that have been used to identify putative cancer stem cell populations. Sphere-forming assays involve plating putative FACS-sorted populations into non-adherent culture conditions. Cells that have stem-like characteristics are believed to form free-floating spheres. This experimental technique has commonly been used to study both stem and cancer stem cell populations in many different tissues. More recently so-called organoid/spheroid *in vitro* assays have been developed that more accurately recreate the tissue architecture present in normal and malignant tissue.

These techniques differ from sphere-forming assays in that they are generally performed by plating cells in a biological extracellular matrix such as collagen or Matrigel™. Rather than forming a nondistinct sphere the matrix allows for the formation of a structure that retains many morphological and cellular features present in the native parental tissue. Using parental intestinal tissue, stem cell-derived organoids have been transplanted back and engrafted into recipient mice with defective intestinal epithelium reforming a functional epithelium (Yui *et al.*, 2012). These types of experiments pave the way for organoids to be used for regenerative medicine approaches.

Historically, the most widely used *in vivo* experimental technique to ascertain whether a cancer cell has clonogenic capacity is xeno/allotransplantation. This approach involves disaggregating a solid human or mouse tumor or a cancer cell line down to the single cell level. This single cell preparation is then FACS sorted using cell surface markers that are hypothesized to mark a cancer stem cell population to generate two populations (cancer stem cell and noncancer stem cell). The two populations are then transplanted using a serial dilution technique into immune compromised animal hosts. The subsequent proportion of tumors that grow and the tumor forming cell frequencies can then be calculated. Generated tumors are then excised, disaggregated again down to single cells and assayed using FACS to see whether the original heterogeneity of the primary has been recapitulated. Importantly the two populations once again undergo FACS sorting and transplantation to formally demonstrate self-renewal. Whilst the experimental technique is sound results can differ significantly based upon the genetic background of the host animal. For example in the situation of melanoma it has been shown that changing the host from a NOD/SCID to NSG (NOD/SCID gamma) raises the frequency of cancer stem cells from 1 in a million to 1 in 4 (Quintana *et al.*, 2010).

One major concern with xenotransplantation and the *in vitro* assays described is they involve taking the cellular populations of interest away from their native environment. It is increasingly apparent that the ‘niche’ is of importance in regulating stem and cancer stemness and further that tumor cells can transition from different states of stemness potential in response to niche signaling (see later). Recent studies using more contemporary experimental approaches such as lineage tracing have shown that some populations identified using traditional approaches as stem or cancer stem-like *ex-vivo*, are, when analyzed *in vivo* using lineage tracing in possession of relatively little clonogenicity (Buczacki *et al.*, 2013). Lineage tracing has become the gold-standard *in vivo* assay for defining stem cell populations in normal tissue (Kretzschmar and Watt, 2012; Blanpain and Simons, 2013). This transgenic strategy generally makes use of a tamoxifen-driven *Cre-Lox* system to induce the permanent expression of a visible reporter whose transcription is driven from the promoter of the gene of interest. If this genetic event occurs within a stem cell then all offspring will also express the reporter generating a long-lived visible clone. If, however, recombination occurs in a transit-amplifying or differentiated cell, then the clone will either be nonexistent or short-lived. This approach has been used successfully in many normal tissues to convincingly identify *bona fide* stem cell populations. Importantly, unlike other techniques the assay is generally accepted as not altering the

niche environment surrounding the targeted population of interest ensuring the results more accurately represent the homeostatic picture. The application of the assay to tumor tissue, however, has been technically difficult, not in the least related to reconstructing clonal hierarchies in a disordered solid structure. Nevertheless, these obstacles have recently been overcome and the first descriptions of cancer stem cells in tumors using lineage tracing have recently been presented in skin papilloma, intestinal adenoma, and glioma (Driessens *et al.*, 2012; Schepers *et al.*, 2012; Chen *et al.*, 2012).

Although generally regarded as not affecting homeostasis, it is worth noting two interesting reports in breast and intestinal tissue that have suggested the commonly used inducing agent in many *Cre-Lox* systems, Tamoxifen, could have unexpected effects on both apoptosis and proliferation in different cell types which could skew subsequent results (Shehata *et al.*, 2014; Zhu *et al.*, 2013). Furthermore, the application of lineage tracing to human tissue is also not straightforward given that it is a transgenic strategy. Indirectly, however, the concept has been used with success in humans by using mutations in mitochondrial DNA to indirectly quantify cancer stem cell dynamics (Humphries *et al.*, 2013). This type of indirect clonal quantification requires significant mathematical involvement as the timing of the recombination event is unknown unlike in *Cre-Lox* systems where it is controlled by the initial Tamoxifen treatment.

Regulation of Cancer Stemness

Although not completely clear it appears that what defines and regulates whether a cell is a cancer stem cell or not may be regulated by the so-called niche. The niche is defined by the cells that are found in close proximity to the tumor cell of interest. These may be epithelial, mesenchymal, infiltrating immunological, or endothelial in origin. The niche can also be altered by more extrinsic factors such as hypoxia. It has been hypothesized that paracrine signaling from surrounding niche cells as well as associated autocrine signaling may determine whether a tumor cell has cancer stem-like properties. This phenomenon has been shown to exist in normal tissues. For example, in the intestine it has been shown that terminally differentiated Paneth cells present in the base of the crypts of Lieberkuhn in the small intestine, actively secrete Wnt proteins (Sato *et al.*, 2011). These same Wnt signals activate neighboring intercalated crypt base columnar cells to achieve the stem-like state. Genetic ablation of Paneth cells subsequently leads to a loss in intestinal stem cell numbers.

In tumors similar observations have also been seen. In glioblastoma it has been demonstrated that xenotransplantation graft rates of Nestin-positive cancer stem cells was higher when endothelial cells from the parental tumor were co-injected (Calabrese *et al.*, 2007). Similarly in head and neck squamous carcinoma, cancer stem cells (ALDH⁺CD44⁺) when exposed to endothelial cell conditioned medium containing endothelial cell-derived growth factors, displayed marked increased proliferation, survival, and self-renewal (Krishnamurthy *et al.*, 2010). In colorectal cancer it has been demonstrated that myofibroblast secreted hepatocyte growth factor (HGF) also results in elevated Wnt signaling and a cancer stem cell-like phenotype (Vermeulen *et al.*, 2010).

It has also been proposed that hypoxia is an important determinant in regulating cancer stemness either directly or indirectly through induction of hypoxia-inducible factor (HIF). CD133⁺ glioma cancer stem cells grown *in vitro* under hypoxic conditions display increased self-renewal and proliferation and inhibition of differentiation through HIF-1alpha expression (Soeda *et al.*, 2009). HIF-1alpha also induces expression of the pro-angiogenic factors VEGF and VEGFR2 required for tumor metastasis (Kuwai *et al.*, 2003). Similarly HIF-1alpha has also been shown to induce the EMT (epithelial to mesenchymal transition) phenotype associated with metastasis and cancer stemness (Gammon *et al.*, 2013). HIF-2alpha also identifies immature (stem-like) cells in breast and neuroblastoma cancers (Pietras *et al.*, 2009). HIF-2alpha effects have been suggested to be governed by downstream activation of the pluripotency gene Oct4 (Covello *et al.*, 2006).

Plasticity

It is increasingly apparent that stemness and in all likelihood cancer stemness is not 'hard-wired' into individual cells. One of the best-known and earliest descriptions of cellular plasticity can be seen in urodeles such as the Salamander. Here, in response to injury a progenitor population (blastema) is generated from apparently terminally differentiated cells. This progenitor population is capable of significant regeneration including complete new limbs. Plasticity on a lesser scale is also evident in mammalian cell populations. This has been demonstrated indirectly in both the hematopoietic and breast systems. More directly using lineage tracing, plasticity in the fate of intestinal secretory progenitor populations reverting to a stem-like state has also been described (Van Es *et al.*, 2012; Buczacki *et al.*, 2013). Plasticity also appears to function within cancer stem cell populations. This can occur remarkably early in the tumorigenesis. Schwitalla recently demonstrated in the intestine that the cell-of-origin of intestinal tumors can be a terminally differentiated enterocyte that can reacquire a stem-like state in response to enhanced NF- κ B expression (Schwitalla *et al.*, 2013). Similar observations have been seen in glioma (Charles *et al.*, 2010). Plasticity may also occur deeper into tumor development. A widely cited example of this occurs in melanoma where cells are capable of reversibly switching on and off the histone demethylase JARID1B (Roesch *et al.*, 2010), JARID1B expressing cells being the population responsible for tumor maintenance.

Truly understanding cellular plasticity in both normal and tumor tissue is now possible using lineage tracing. Indeed lineage tracing has shown that many of the conclusions using historical *in vitro* and *in vivo* assays such as xenotransplantation and organoid growth are not entirely reliable in identifying true clonogenic function rather than potentiality. It appears that many of these assays in reality quantify the latter rather than the cells' true *in vivo* behavior.

Markers for the Identification of Cancer Stem Cells in Major Malignancies

Cancer stem cells have now been identified in most solid organ malignancies. The majority of these reports have made

use of FACS sorting and xenotransplantation of putative cancer stem cell populations using cell surface markers. There is significant overlap in these markers between solid tumors implying conserved pathways and functionality (Buczacki *et al.*, 2011).

Leukemia – Leukemic cancer stem cells were amongst the first cancer stem cells to be described. Initially described in acute myeloid leukemia (AML) by Bonnet and Dick they are characterized by expression of CD34⁺ and CD38[−]. Since this initial discovery the use of mice strains with higher degrees of immune-deficiency such as NOD/SCID/ $\beta 2m^{-/-}$ or NOD/SCID/IL2R $\gamma^{-/-}$ have enabled increased engraftment efficiencies of CD34⁺/CD38[−] Lin[−] cancer stem cell populations as well as progenitor CD34⁺/CD38⁺ Lin[−] populations (Taussig *et al.*, 2008). These and other experiments demonstrate heterogeneity in the leukemic stem cell population.

Breast – Breast cancer stem cells were initially described based on the finding that FACS sorting CD44⁺/CD24^{−/low} Lin[−] cells enriched for a cell population which had significantly higher engraftment rates than alternatively FACS-sorted populations (Al-Hajj *et al.*, 2003). Aldehyde dehydrogenase (ALDH) has also been described as a marker that enriches for breast cancer stem cells (Ginestier *et al.*, 2007). Additionally, CD133 (Prominin-1) and CD29 have been proposed as breast cancer stem cell markers (Wright *et al.*, 2008; Vassilopoulos *et al.*, 2008).

Colorectal – Colorectal cancer stem cells have been proposed to be identified by the following markers: CD133 (Ricci-Vitiani *et al.*, 2007; O'Brien *et al.*, 2007), CD44 (Dalerba *et al.*, 2007), CD24 (Vermeulen *et al.*, 2008), CD166 (Dalerba *et al.*, 2007), Dcl1 (Nakanishi *et al.*, 2013), Lgr5 (Schepers *et al.*, 2012), and Olfm4 (Van Der Flier *et al.*, 2009). Recently two of these, Lgr5 and Dcl1, have been shown using lineage tracing to mark a cancer stem cell population in murine adenomas. These two markers are believed to have significant overlap in expression.

Brain – Neuronal cancer stem cells have been reported to be marked by CD133 (Singh *et al.*, 2004), Nestin (Chen *et al.*, 2012) as well as Bmi1 (Bruggeman *et al.*, 2007). Only Nestin, however, has been confirmed using lineage tracing to specifically mark clonogenic tumor cells. This recent publication showed that a relatively quiescent Nestin-expressing population of cancer stem cells becomes activated after temozolomide chemotherapy thus potentially accounting for disease recurrence after adjuvant therapy.

Ovarian – Whilst several markers including CD24 (Gao *et al.*, 2010), CD133 (Ferrandina *et al.*, 2009), and ALDH (Kryczek *et al.*, 2012) have been used to identify cancer stem cell-like populations in ovarian cancer, the cell-of-origin for these tumors has remained contested; some proposing that the tumor arises within the distal end of the fallopian tube rather than the ovary *per se*. Using lineage tracing it has been demonstrated that in some ovarian tumors this founder cancer cell appears to originate from the ovarian surface epithelium and is marked by expression of Lgr5 and ALDH (Flesken-Nikitin *et al.*, 2013). Whether this is the case for all ovarian tumors remains to be determined.

Skin – The only other system where putative cancer stem cells have been identified using lineage tracing is in the skin (Driessens *et al.*, 2012). Using mathematical analysis of clone

formation driven by a non-cell type specific promoter, in chemically induced skin papillomas the authors found two patterns of division. One of these modes of division generated long-lived clones suggesting stem cell-like behavior. It should be noted, however, that this study was performed in papilloma which whilst being neoplastic is not truly invasive.

Others – Cancer stem cells have also been described in tumors of the lung, prostate, pancreas, and liver using markers such as ALDH (Liang and Shi, 2012), CD133 (Collins *et al.*, 2005), CD44 (Yao *et al.*, 2010), and CD24 (Yao *et al.*, 2010).

Although cell surface markers have historically been of tremendous value in FACS/xenografting experiments it is important to note that many of these markers do not uniquely identify cancer stem cell populations. Indeed many of these markers such as CD24 are signaling pathway target genes and thus reflect a population where a specific signaling pathway is active. This results in the population sorted using a cell surface marker such as CD24 being relatively heterogeneous encompassing both cancer stem cell populations as well as more differentiated progeny. Furthermore, the use of cell surface markers alone will not enable the characterization of plasticity within cancer stem cell populations where a more differentiated cell type may not be marked by a specific marker but may, however, still retain stem cell potency.

Clinical Significance of Cancer Stem Cells

Over the last decades the concept of cancer stem cells has developed from being a hypothesized population to a real definable entity. What is still unclear is what provides a cancer stem cell its unique identity and how prevalent they are throughout tumor development. Indeed, in light of context-dependent plasticity the true prevalence of a cancer stem cell population at any one point in time may be irrelevant as this will be a dynamic and ever changing figure. Importantly, this dictates that classical clinical modes of detecting tumor types such as immunohistochemistry (IHC) will be inappropriate for quantifying cancer stem cell prevalence in this context. Nevertheless, the presence of this unique cell population does provide an important clinical target for therapeutic targeting. In addition to their clonogenic capacity cancer stem cells display many attributes that predispose to drug resistance such as enhanced DNA repair pathways, cellular dormancy, and the expression of multidrug resistance proteins. These faculties suggest that targeting this population may be problematic. Indeed many authors suggest that these attributes may suggest that cancer stem cells are the population responsible for disease recurrence after adjuvant therapy. Late systemic recurrence is not uncommon after apparent complete response. Clearly, for this to occur requires a small, drug resistant and highly clonogenic population to exist – just as cancer stem cells appear to be. It has been proposed however that given many cancer stem cell populations share a large number of molecular features with regular stem cells; direct targeting of these cells could lead to significant deleterious effects on the associated normal tissue homeostasis. In the context of the gut this question has recently been answered in reference to the nature of doublecortin-like kinase 1 (Dcl1) expressing cells. Early reports had suggested that Dcl1 marked a putative quiescent

intestinal stem cell population; however, others had argued that Dclk1 marked a rare terminally differentiated secretory cell type called a Tuft cell (May *et al.*, 2009; Gerbe *et al.*, 2009). Dclk1 expression has also been described in both murine and human intestinal tumors. Using a lineage tracing technique it has now convincingly been shown that in the normal intestine during homeostasis Dclk1 expressing cells are indeed terminally differentiated. However, during dextran sulfate sodium (DSS) treatment or radiation-induced epithelial injury a very small proportion of these cells can acquire stem cell capacity characterized by the ability to generate long-lived clones (Nakanishi *et al.*, 2013). Interestingly when cancer stem cell capacity is quantified in tumor bearing Apc^{Min} mice, Dclk1 expressing cells also generate many clones implying a strong cancer stem cell-like phenotype. Intriguingly, targeting these Dclk1 expressing cells specifically using transgenic expression of diphtheria toxin receptor and then diphtheria toxin treatment leads to tumor regression without any deleterious effect on the associated normal intestinal epithelium. These data contrast with many other reports in showing widely differing functions of marker defined cells dependent on an oncogenic/normal tissue context.

Using knowledge about the molecular mechanisms underpinning regular stem cell function it has been shown that disrupting similar modes of self-renewal in cancer could lead to therapeutic advantage (Kreso *et al.*, 2014). Bmi1 (part of the polycomb repressive complex 1) appears to mark stem cells in many tissues. Interestingly, both siRNA and small molecule knockdown of Bmi1 leads to diminishment in tumor growth both *in vitro* and in xenograft experiments using colorectal cancer tissue without significant effect on the overall health of the animal. These data intriguingly draw together a potential cancer stem cell marker which additionally has a significant functional role.

Alternative approaches using differentiation therapy have also been suggested. These rely on a more generalized treatment that causes undifferentiated cancer stem cells to undergo a differentiation program. This approach has been used for many years for patients suffering with acute promyelocytic leukemia using a drug called all-*trans* retinoic acid (ATRA). The approach has also been experimentally described in the intestine using BMP4 treatment to differentiate cancer stem cells in colorectal cancer xenografts where in addition to promoting apoptosis and differentiation the treatment also chemosensitized the tumors (Lombardo *et al.*, 2011).

Conclusions

Improved experimental techniques, first used in normal stem cell biology, such as lineage tracing have enabled more detailed and accurate descriptions of cancer stem cell behavior. Nevertheless, it is only very recently that combined genetic and functional approaches are being used to understand the behavior of these cells. These approaches are essential to better correlate genetic makeup with phenotypic function. Clearly now cancer stem cells are recognized as a real entity they are also an important clinical target whose eradication will improve the efficacies of adjuvant therapy. In the future, indirect approaches such as differentiation therapy and niche

manipulation will be as important as direct targeting in eliminating this unique cell population.

Metabolic and Energetic Regulation of Stem Cells

The unique properties of stem cells, namely their ability to self-renew, to persist throughout the life of the organism, and to exist for a long period of time in a quiescent state, suggest that this cell type might have unique metabolic constraints. Because of their clinical importance and their experimental tractability, much of our knowledge regarding stem cell metabolism comes from the hematopoietic stem cell (HSC) system. The earliest foray into this area was precipitated by attempts to understand the role of oxygen in the biology of HSCs. Like all adult stem cells, HSCs have the capacity to give rise to multipotent progenitors, or to produce new stem cells (Figure 1). The latter process is termed self-renewal and experimentally this activity in HSCs can be assessed by the ability of bone marrow cells to repopulate lethally irradiated host animals. Early experiments demonstrated that the repopulating ability of HSCs was improved when cells were maintained under low-oxygen conditions (Cipolleschi *et al.*, 1993; Danet *et al.*, 2003). This was followed by various theoretical calculations that posited that the oxygen gradient in the bone marrow was such that long-term HSCs most likely resided in near hypoxic conditions (Chow *et al.*, 2001). These mathematical models were subsequently solidified by experimental evidence. Initial efforts were hampered by the inability to do true *in vivo* analysis. Nonetheless, using the weak base pimonidazole that acts as a functional and immunohistochemical marker of hypoxia, it was demonstrated that within all the diverse cell types of the bone marrow, HSCs appear to be the most pimonidazole-positive (Parmar *et al.*, 2007). Subsequent quantitative *in vivo* imaging confirmed many of these earlier observations (Nombela-Arrieta *et al.*, 2013).

Figure 1 General biology of adult stem cells. Stem cells are unique in their capacity to divide and give rise to two different types of daughter cells. This asymmetric cell division includes giving rise to a multipotent progenitor cell, as well as to a new stem cell. The latter process is termed self-renewal. For the case of HSCs, multipotent progenitor cells can give rise to all blood forming cells, including red cells, white cells, and platelets.

These experiments, most recently using 3D reconstitution of the bone marrow niche, revealed that the microvessels surrounding HSCs appear to represent a unique vasculature configuration. Interestingly, HSCs appeared to be pimonidazole-positive irrespective of their distance from the vasculature. This argues that the 'hypoxic' nature of bone marrow stem cells may not relate solely to the distance of the HSC from a blood vessel, but rather may reflect an intrinsic quality of the stem cell.

Hypoxia-Inducible Factor 1 α and Glycolysis in Stem Cells

Given the relative rarity of HSCs within the bone marrow, it was initially difficult to perform classical metabolomics analysis on this rare cell type. Nonetheless, some early certain key and informative measurements were made. Initial experiments demonstrated that when compared to total bone marrow, the oxygen consumption and ATP levels were lower in bone marrow fractions enriched for HSCs (Simsek *et al.*, 2010). Furthermore, when glycolytic flux was determined by measuring the amount of glucose-derived ^{13}C -lactate production, HSCs appeared to have increased rates of glycolysis. This suggested that HSCs may limit normal mitochondrial metabolism and in ways perhaps similar to tumor cells, adapt a metabolic profile that relies on the cytosolic metabolism of glucose. Indeed, using mitochondrial membrane potential (ψ_m) as a marker, it was shown that HSCs exhibit constitutively low ψ_m , consistent with a program of de-energize and inactive mitochondria (Simsek *et al.*, 2010). This might be a common property of stem cells, as earlier experiments in embryonic stem cells reached similar conclusions (Schieke *et al.*, 2008).

Given the relative hypoxic environment and their reliance on glycolysis for energy, it seemed reasonable that the hypoxia-inducible factor 1 α (HIF-1 α) transcription factor might play a central role in the biology of HSCs. HIF-1 α is the oxygen-sensitive component of the heterodimeric transcription factor HIF-1. HIF-1 serves as the central coordinator of the cellular and systemic response to a low-oxygen environment (Wang and Semenza, 1995). Classically, HIF-1 regulates the expression of a host of enzymes involved in glycolysis, including aldolase A, enolase 1, lactate dehydrogenase A, phosphofructokinase 1, and phosphoglycerate kinase 1 among others (Iyer *et al.*, 1998). This adaptation allows the cell to produce ATP in the setting of a low-oxygen environment. Levels of HIF-1 message and protein are indeed elevated in HSCs (Simsek *et al.*, 2010; Takubo *et al.*, 2010). Furthermore, conditional bone marrow deletion of HIF-1 α results in an increased fraction of HSCs emerging from quiescence (Takubo *et al.*, 2010). Gain-of-function studies, leading to increase HIF-1 α levels, revealed that this genetic manipulation led to an increase in the fraction of cells in the quiescent G0 phase of the

cell cycle (Takubo *et al.*, 2010). Thus, the quiescent state of HSCs is intimately connected to the metabolic state of these cells. Interestingly, cells without HIF-1 α demonstrate impaired stress resistance as evidenced by their inability to contribute to hematopoiesis after serial transplantation or during normal aging. Similarly, while cells with too much HIF-1 α exhibited impaired functional properties after transplantation, suggesting that the level of HIF-1 α needs to be tightly regulated within stem cells in order to maintain optimal function (Takubo *et al.*, 2010).

Recent data have solidified the connection between metabolism and stemness (i.e., the ability to both self-renew and give rise to committed progenitor cells) within the HSC population. In particular, a recent study demonstrated an essential role for the family of glycolytic regulatory enzymes known as pyruvate dehydrogenase kinase (Pdk) (Takubo *et al.*, 2013). The activity of the mitochondrial enzyme pyruvate dehydrogenase (PDH) is essential for the critical conversion of pyruvate to acetyl-CoA, the entry step for glucose into the tricarboxylic acid (TCA) cycle (Figure 2). The activity of PDH is regulated at many levels, including the ability to be inhibited following phosphorylation by the Pdk. Using loss- and gain-of-function models, this recent study has again demonstrated a role for glycolytic metabolism in maintaining HSC quiescence and functional capacity. Using a significant number of mice ($n=120$) the authors were able to purify approximately one million stem and progenitor cells and then perform a metabolomics assessment. Compared to more mature bone marrow-derived cells, HSCs and their immediate descendants demonstrated elevated levels of fructose 1,6-bisphosphate, a known intermediary of glucose metabolism, while levels of TCA intermediates were reduced (Takubo *et al.*, 2013). These metabolic data are once again consistent with a

pattern of using glycolysis, rather than mitochondrial metabolism to fuel the resting HSC energy demands. It was further shown that HIF-1 α regulates the transcript levels of Pdk2 and Pdk4 in HSCs. Mice deficient in Pdk2 and Pdk4 (Pdk2^{-/-}Pdk4^{-/-} mice) had a fall in steady state pyruvate levels consistent with a role for the Pdk in normally restraining mitochondrial activity. This increase in mitochondrial metabolism (and corresponding reduction in glycolysis) was accompanied by a shift from G0 to G1 in the HSC population. Following transplantation, Pdk2^{-/-}Pdk4^{-/-} HSCs demonstrated impaired self-renewal capacity. This was particularly evident after a second round of transplantation (Takubo *et al.*, 2013). Thus, once again, the ability to maintain glycolytic flux appears critical to maintain HSC function.

Fatty Acid Metabolism and Mitochondrial Function

While glycolytic flux appears to play a critical role in HSC self-renewal, glucose metabolism is not the sole determinant of HSC function. Recent evidence also suggests that fatty acid oxidation (FAO) can also regulate HSC function (Ito *et al.*, 2012). Again, using a mouse model, investigators were able to interrupt mitochondrial fatty acid metabolism either genetically (through the loss of peroxisome proliferator-activated receptor δ) or pharmacologically (through the action of the FAO inhibitor, etomoxir). Interestingly, while the preceding discussion has emphasized the apparent reliance on cytosolic glycolysis, bone marrow cells enriched for HSCs appear to be capable of undergoing appreciable rates of FAO (Ito *et al.*, 2012). Inhibition of FAO impaired donor-derived reconstitution after transplantation consistent with a role for fatty acid metabolism in self-renewal. Interestingly, using a single cell assay the authors were able to assess symmetrical versus asymmetrical cell division. Disrupting FAO led to an increase in frequency of stem cells undergoing symmetric commitment (i.e., given rise to two committed daughter cells), a shift again consistent with the observed defect in self-renewal. This *in vitro* assay suggests that FAO is involved in the poorly understood decision as to whether stem cells self-renew or give rise to committed progenitors.

Another recent link between mitochondrial function and HSC biology come from the analysis of cells deficient in the expression of the mitochondrial phosphatase PTPMT1 (Yu *et al.*, 2013). This inner mitochondrial protein is a phosphatase and tensin homolog (PTEN)-like phosphatase that metabolizes phosphatidylinositol phosphatases (PIPs). PIPs are a general class of lipid mediators that regulate a wide array of cellular functions from trafficking to channel activity. While relatively little is known about the role of PIPs in the mitochondria, it is known that PTPMT1 deletion results in early embryonic lethality (Shen *et al.*, 2011; Zhang *et al.*, 2011). Using a conditional knockout approach, it was later demonstrated that hematopoietic-specific PTPMT1 deletion resulted in pancytopenia and rapid postnatal death (Yu *et al.*, 2013). While the levels of differentiated cells were markedly reduced (consistent with the pancytopenia), analysis of the bone marrow of conditional PTPMT1 deleted mice revealed that the number of HSCs were surprisingly elevated (by approximately 40-fold). Cell cycle analysis revealed that PTPMT1-deficient

Figure 2 A central role for HIF-1 α in regulating HSC biology. The transcription factor HIF-1 α plays a central role in regulating the metabolic state of HSCs. This occurs through multiple mechanisms including increasing glycolytic flux and increase in glucose uptake and a transcriptional increase in the levels of key glycolytic enzymes. In addition, by regulating the expression of various PDK family members, HIF-1 α can also negatively regulate PDH activity, and thereby regulate TCA-dependent metabolism.

HSCs had emerged from G0 at an elevated rate compared to control cells, yet seemed to be trapped in G1. Consistent with this cell cycle arrest, PTPMT1 cells functioned poorly in transplantation assays. Metabolic assessment revealed that deletion of PTPMT1 resulted in reduced mitochondrial metabolism leading to energetic stress, at least as assessed by activation of AMP-activated kinase (AMPK). Reconstitution of various mutants into a knockout background revealed that the mitochondrial localization, as well as the catalytic function of PTPMT1, was necessary to restore functional HSCs. Interestingly, deletion of PTPMT1 in more committed myeloid, T cell, or B cell progenitors had no discernable effect. Thus, mitochondrial activity is required for HSC differentiation at the earliest stem cell and/or progenitor stage, while such activity is seemingly dispensable at later progenitor or mature cell stages.

Nutrient-Sensing Pathways

Taken together, these studies demonstrate that both mitochondrial and non-mitochondrial metabolism regulate key aspects of HSC function. Less clear from these observations is how metabolic programs are encoded and how energetic signals are transduced. One classical pathway that regulates nutrient signaling, especially downstream of growth factors, involves the sequential activation of phosphatidylinositol 3-kinase (PI3K), protein kinase B (AKT), and mechanistic target of rapamycin (mTOR). Relevant to the preceding discussion, the PTEN phosphatase is a known negative regulator of this pathway. Genetic evidence suggests that this pathway is clearly relevant to HSC biology. For instance, constitutively activated AKT1 leads to HSC exhaustion and high rate of development of leukemia (Kharas *et al.*, 2010). Interestingly, these animals are protected when they are administered the mTOR inhibitor rapamycin. Similarly, mice with a conditional deletion of PTEN within the bone marrow demonstrate an initial expansion, followed by the long-term exhaustion, of HSCs (Zhang *et al.*, 2006; Yilmaz *et al.*, 2006). Again, these mice appear to develop a premalignant expansion of bone marrow cells that is rescued by rapamycin treatment (Yilmaz *et al.*, 2006). This suggests a role for mTOR in HSC maintenance. Indeed, genetic removal of tuberous sclerosis 1 (Tsc1), a known negative regulator of mTOR, results in the activation of mTOR and the exit of HSCs out of quiescence and into a pattern of rapid cell cycling (Chen *et al.*, 2008a; Gan *et al.*, 2008). As such, activation anywhere along the PI3K, AKT, and mTOR pathways results in a disruption of the normal quiescence of HSCs with an initial expansion of stem and progenitor cells, followed by their premature exhaustion. The fact that manipulation of this pathway also results in premalignant conditions that mimic myeloproliferative disorders, or frank leukemia, suggests that inhibition of this axis might be of benefit to a wide swath of patients with hematological malignancies.

Another critical pathway for nutrient sensing in stem cells involves LKB1-AMPK signaling. While for the sake of clarity this pathway is discussed separately, it is important to note that AMPK regulates mTOR activity, and that both AKT and AMPK regulate the activity of the forkhead homeobox type O (FoxO) family of transcriptional regulators. As such,

Figure 3 Interconnection between various energy sensors and transducers involved in stem cell function. Relationship between various kinases, phosphatases, and transcription factors each separately implicated in the biology of stem cells and in metabolic and redox homeostasis. See text for details.

LKB1/AMPK and PI3K/AKT/mTOR are integrated nutrient sensing pathways (Figure 3). The LKB1 kinase was initially characterized as the causal mutated gene in the familial cancer syndrome known as Peutz-Jeghers syndrome. This autosomal dominant disease is characterized by a hamartomatous polyposis syndrome (hence the increased risk for malignancy), as well as hyperpigmented macules on the lips and mouth. What role stem or progenitor cell activation plays in this proliferative disease is unclear. Genetic evidence suggests that LKB1 is upstream of AMPK. The activation of AMPK is generally viewed to occur when the AMP/ATP ratio is increased (i.e., during periods of energetic stress). Once activated, AMPK subsequently phosphorylates and often inactivates a number of energy requiring processes, including reducing the activity of mTOR. Much like what was observed for components of the PI3K/AKT pathway, conditional deletion of LKB1 leads to an initial burst of HSC activity, followed by their eventual exhaustion (Gan *et al.*, 2010; Gurumurthy *et al.*, 2010; Nakada *et al.*, 2010). The precise mechanism of this effect however remains elusive. While the obvious candidate would seem to be constitutive activation of mTOR, rapamycin was without effect. Similarly, as we will discuss later, while alterations in FOXO signaling can lead to oxidative stress, antioxidant treatment did not rescue *Lkb1* depletion in the bone marrow. Indeed, these three studies in which *Lkb1* was deleted in the bone marrow demonstrated that the observed effects on HSC biology appeared largely independent of AMPK, mTOR, or FoxO proteins. While the downstream effector remains somewhat elusive, some evidence suggests that LKB1 may act by altering mitochondrial biogenesis (Gan *et al.*, 2010) or potentially by altering lipid metabolism (Gurumurthy *et al.*, 2010).

Redox Homeostasis

Why is it that intracellular metabolism and stem cell biology are so tightly linked? At present, there is no definitive answer. One possibility is that adult stem cells need to persist for the life span of the organism, and as such need to develop mechanisms to reduce genomic damage. Since the endogenous

production of reactive oxygen species (ROS) is thought to fuel DNA damage, as well as potentially the aging process, tight metabolic regulation may be essential to maintain stem cell function throughout the organism's life span. Indeed, the fact that quiescent HSCs reside in a relatively hypoxic environment and seem to use their mitochondria only sparingly would seem like the ideal environmental conditions to reduce ROS production.

The connection between ROS levels and HSC function has been known for some time. Using the fluorescent compound dihydrodichlorofluorescein (DCF) it has been possible to obtain an understanding of redox regulation within bone marrow cells. The compound DCF is not initially fluorescent, however when oxidized by molecules such as hydrogen peroxide, a stable, fluorescent molecule is produced. As such, the level of DCF fluorescence is often used as a marker for intracellular ROS levels. An important caveat is that many believe that DCF is not directly oxidized by hydrogen peroxide and, therefore, not a reliable indicator of peroxide levels (Dikalov and Harrison, 2014). Nonetheless, largely due to practical issues involving the relatively few numbers of cells, this has been the predominant strategy employed. For instance, sorting HSCs based on DCF fluorescence (DCF^{high} meaning high levels of ROS and DCF^{low} corresponding to low levels of ROS) revealed that DCF^{low} cells had increased functionality following posttransplant reconstitution (Jang and Sharkis, 2007). Moreover, the DCF^{high} fraction appeared to be myeloid skewed, i.e., to produce more myeloid derivatives at the expense of lymphoid derivatives. Interestingly, this is a well-known property of aging bone marrow cells, a functional property observed in both mice and man. These observations solidified the well-known relationship between oxidants and senescence (Liang and Ghaffari, 2014).

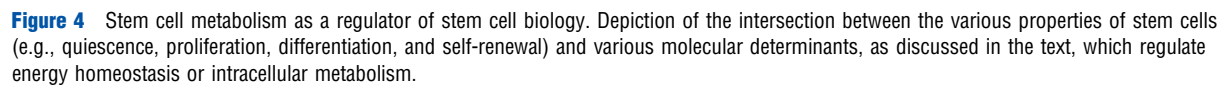

Another clear link between ROS homeostasis and HSC biology came from the analysis of mice lacking the gene encoding for the ataxia-telangiectasia mutated (ATM) kinase. This kinase has been implicated in the crippling disease ataxia-telangiectasia, characterized by a wide array of defects including neurological abnormalities, cancer predisposition, and an accelerated aging phenotype. ATM kinase plays a central role in coordinating the response to DNA damage, particularly the response to double strand breaks in the DNA. *Atm*^{-/-} mice recapitulate certain aspects of the human disease including the cancer predisposition. Most *Atm*^{-/-} mice succumb in the first few months of life to lymphoid malignancies. For those mice who manage to survive beyond the first several months, it was observed that a picture of progressive bone marrow failure developed (Ito *et al.*, 2004). Further experimentation revealed that *Atm*^{-/-} HSCs had impaired self-renewal. Using DCF, it was shown that deletion of *Atm* results in increased levels of ROS within the stem and progenitor population (Ito *et al.*, 2004). The addition of the antioxidant *N*-acetyl cysteine (NAC) that acts to replenish glutathione levels was able to preserve self-renewal capacity of *Atm*-deficient HSCs. Subsequent studies established that *Atm* deletion resulted in the redox-dependent activation of the p38 MAPK pathway, that in turn, resulted in the induction of the cell cycle inhibitor p16 (also known as INK4A) (Ito *et al.*, 2006). Again, similar to what was observed with NAC treatment, pharmacological p38 MAPK inhibitors improved HSC function (Ito *et al.*, 2006).

Furthermore, overexpression of the Polycomb gene *Bmi1*, known to epigenetically silence the *CDKN2A* locus that encodes p16, could also rescue the HSC defect in *Atm*^{-/-} mice (Ito *et al.*, 2004). In contrast to the rescue seen with *Bmi1* overexpression, deletion of *Bmi1* leads to defects in HSC self-renewal (He *et al.*, 2009). Interestingly, the loss of *Bmi1* also leads to increased levels of ROS (Liu *et al.*, 2009; Chattoo *et al.*, 2009).

Another important link between ROS levels and HSC function comes from the analysis of mice lacking members of the FoxO family of transcription factors. This family has four members that include FoxO1, FoxO3a, FoxO4, and FoxO6. Previous evidence suggested that this family was critical to maintaining redox homeostasis, as for instance, FoxO3a can induce the expression of antioxidant enzymes including catalase (Nemoto and Finkel, 2002) and superoxide dismutase (Kops *et al.*, 2002). Analysis of mice simultaneously deleted for three FoxO family members (FoxO1^{-/-}, FoxO3a^{-/-}, and FoxO4^{-/-}) demonstrated a reduction in HSC numbers over time and a reduced ability for FoxO-deficient cells to self-renew (Tothova *et al.*, 2007). Consistent with previous observations, the absence of FoxO proteins resulted in decreased levels of antioxidant defense proteins and a corresponding increase in the level of ROS. Like what was observed for *Atm*^{-/-} mice, mice deficient in FoxO activity could be rescued by NAC treatment. Similar observations were made in mice lacking a single FoxO member (FoxO3a) (Miyamoto *et al.*, 2007). Again, there was a defect in HSC function that appeared to be secondary to a rise in ROS levels and potentially to the subsequent redox-dependent activation of p38 MAPK.

Other Stem Cell Niches

Our discussion so far has dealt almost exclusively with HSCs. This is largely because this experimental model is the most widely used and studied. Nonetheless, many of the lessons learned from this system appear to be applicable to other stem cell niches. For instance, cultured embryonic stem cells appear to exhibit high rates of glycolysis (Kondoh *et al.*, 2007). Interestingly, in the induced pluripotent stem cell (iPSC) system, a shift from mitochondrial metabolism to glycolysis appears to accompany, and be required, for high efficiency reprogramming of somatic cells to stem-like iPSCs (Folmes *et al.*, 2011). A similar situation appears to exist for mesenchymal stem cell (Chen *et al.*, 2008b). In addition, the energy sensing and redox-regulating pathways discussed within the context of HSCs are often applicable to other stem cells. For instance, as seen in the case of HSCs, deletion of FoxO3 in neural stem cells (NSCs) results in impaired self-renewal, again through activation of a redox-sensitive pathway (Renault *et al.*, 2009; Paik *et al.*, 2009). Similarly, there appears to be an important role of FAO and fatty acid synthesis in diverse stem cell niches (Ito and Suda, 2014). This may be in part because FAO helps to maintain levels of NADPH required for redox homeostasis (Jeon *et al.*, 2012). Similarly, the maintenance of adult NSCs is dependent on fatty acid synthesis (Knobloch *et al.*, 2013). In addition, the mTOR pathway has been recently shown to play a role in the maintenance of muscle stem cell quiescence (Rodgers *et al.*, 2014). Nonetheless, while many pathways

epigenetic state. Given the critical role of epigenetics in maintaining 'stemness,' as well as aiding the program of differentiation, it would seem that there is much to learn about the convergence of intracellular metabolism and stem cell biology. Such insights may provide important clues on the origin of cancer, as well as how it might be possible to rationally delay the age-dependent decline in stem cell function.

Pluripotent Cells: New Tools for Disease Research and Therapies

TD Tlsty, University of California, San Francisco, CA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Pluripotent A cellular state where differentiation is possible into each of the three germline derivatives.

SON A mutually regulated pathway of three proteins, SOX2, OCT3/4, and Nanog, that confers pluripotent potential to a cell.

Naturally Occurring Pluripotent Cells

By definition, cells within a pluripotent state can form tissue derivatives of the three embryonic germ layers (ectoderm, mesoderm, and endoderm) (Blau *et al.*, 2001). This is in contrast to multipotent cells whose offspring are restricted to forming organ-specific cells and totipotent cells that have the potential to generate all embryonic, as well as extraembryonic, tissues such as placenta. The first commonly studied pluripotent cell was the embryonic stem cell (ESC), first isolated from mice and teratocarcinomas in 1981 (Martin, 1981; Evans and Kaufman, 1981). Isolation of human embryonic stem cell (hESC) followed several years later (Thomson *et al.*, 1998). The primary source of pluripotent ESCs is the inner cell mass of the blastocyst irrespective of whether the animal is an amphibian or mammal. As the ESCs within the blastocyst are programmed to lose pluripotent capacity with maturation of the embryo, the genital ridge gives rise to embryonic germ cells (EG) or primordial germ cells (PGC) which also exhibit pluripotent capability. Spermatogonial germ stem cells are a further source of pluripotent cells.

Surprisingly, other, more differentiated, cells within the fetal and adult mammalian body have also been reported to have pluripotent potential. These include fetal mesenchymal fibroblasts, placental cord blood, and mesenchymal stem cells (MSCs) (Kues *et al.*, 2005; Kogler *et al.*, 2004; Lee *et al.*, 2004). More recently, it has been reported that numerous adult tissues contain cells with pluripotent potential. Skin progenitor cells (SKP), multipotent adult progenitor cells (MAPC), marrow-isolated adult multilineage inducible (MIAMI) cells, and very small epithelial-like cells (vSELs) are just a few of the examples (Toma *et al.*, 2001; Jiang *et al.*, 2002a; D'Ippolito *et al.*, 2004; Ratajczak *et al.*, 2011). Most recently, it has been demonstrated that rare cells within multiple human adult tissues respond to wounding by proliferating and exhibiting pluripotent potential. Thus, multilineage differentiating stress enduring (MUSE) cells (Kuroda *et al.*, 2010) and endogenous plastic somatic (ePS) cells (Roy *et al.*, 2013) may contribute to wound healing. The isolation and characterization of human amnion epithelial cells and amniotic fluid stem cells has been extensively described and is being tested in organ reconstruction studies (Murphy and Atala, 2013). These reports demonstrate that pluripotency is not a phenotype that is restricted to ESCs or a specific developmental phase, a still controversial conclusion.

Engineered Pluripotent Cells

For many decades it was believed that cell differentiation was irreversible. Conventional wisdom held that pluripotent ESCs

would commit to one of the three primary lineages and further restriction of differentiation potential would progress from that point forward. In the early 1950s, Briggs and King (1952) transplanted blastula nuclei into enucleated frog eggs and obtained viable tadpoles, paving the way for John Gurdon to determine if the nucleus of a fully differentiated cell was irreversibly altered during cell differentiation using somatic cell nuclear transfer (SCNT). Transplantation of a nucleus from an intestinal cell of a tadpole into an enucleated egg produced a low number of normal adult frogs demonstrating a fundamental and general principle that cell differentiation can take place without stable changes to the genome (Gurdon, 1962a,b). These studies have been extended to mammalian nuclei and demonstrate that a terminally differentiated cell can be reprogrammed to totipotency (Wilmut *et al.*, 1997; Hochedlinger and Jaenisch, 2002).

Molecular *in vitro* investigations into the mechanisms that allow cells to reverse differentiation and acquire pluripotency generated surprising results. Pluripotency as well as specific cell types are specified by transcription factors. In 2006, a team led by Yamanaka reported that four transcription factors (OCT4, SOX2, Klf4, and c-Myc) were sufficient to take a fibroblast nucleus to a pluripotent state (Figure 1; Takahashi and Yamanaka, 2006). In a slightly different approach, the Thompson team reported that expression of OCT4, SOX2, NANOG, and LIN28 would accomplish the same goal (Yu *et al.*, 2007). Reprogramming using these methods are slow and proceed with very low efficiency. Major changes in gene expression and epigenetic states are obvious. To claim pluripotent potential, the resulting induced pluripotent stem cells (iPSCs) were required to express classic ESC-specific proteins and cell surface antigens, differentiate into derivatives of all three germ lineages *in vitro*, and generate teratomas when injected into immune-compromised mice. The teratomas must contain differentiated derivatives of all three primary germ layers (ectodermal, mesodermal, and endodermal) and be able to contribute to the next generation of offspring (Thomson *et al.*, 1998).

Having established that differentiated cells are not irreversibly locked in their mature or terminal identity *in vitro* but may be activated to generate any and all other cell types of the body, the question becomes how, when, and where may this expression of pluripotency occur? Additionally, is pluripotency expressed more widely *in vivo* than previously believed?

New Tools to Provide Mechanistic Insights on Determining Cell Fates and Disease States

The existence of pluripotent cells has provided an important tool for studying the mysteries of developmental biology and

Figure 1 Pluripotent cells as tools for disease research and therapies. The red arrows indicate the methodological route taken to produce human embryonic stem cells (hESCs). An adult cell is removed from the body and the nucleus is transferred to an enucleated oocyte. The resulting ESCs can be used for generating different cell types that can subsequently be utilized for drug screening or tissue reconstruction as part of *in vitro* preclinical modeling. Additionally, the intention is that they will also be useful for transplantation into recipients in need of cell-based therapies. The blue arrows indicate the initial methodological route taken to produce human induced pluripotent stem cells (iPSCs). A cocktail of transcription factors are introduced into adult differentiated cells and rare pluripotent cells are generated. Multiple combinations of transcription factors have now been found to be effective in generating embryonic pluripotent stem cells (ePSCs). Attempts of chemical induction of pluripotency are underway. Similar to ESCs, the intention is that iPSCs will also be useful for transplantation into recipients in need of cell-based therapies. Finally, the green arrows indicate the methodological route taken to enrich human cells with pluripotent potential that have been reported to reside within the body. While these cells can also be used in a manner similar to that described for ESCs or iPSCs, endogenous pluripotent cells have additional options. Since they reside *in situ*, it may someday be possible to program these cells to desirable derivatives without removing them from the body.

the generation of tissues (Hough *et al.*, 2014; Ohnishi *et al.*, 2014). Pluripotent cells have tremendous potential for use in preclinical modeling of human diseases as well as providing an experimental system to screen for effective drugs. For example, patient-derived iPSCs may be used as a primary source of cellular material for correction of molecular defects through genetic engineering. The ‘repaired’ cell may then be differentiated and coupled with cell therapy (see below) so the corrected derivatives may be returned to the donor. Diseases such as metabolic syndromes (Pompe’s disease or glycogen storage disease 1a) where cells lack specific enzymes used to generate cellular building blocks could be corrected in this manner. Additionally, the use of this technology to generate cells with a disease-relevant phenotype is groundbreaking. If the redifferentiated cell phenocopies the disease trait in the original patient, this material could then be used for screening of drugs or disease-modeling *ex vivo*. Typically many types of diseases cannot be studied for lack of access to appropriate human cells that exhibit the critical phenotype. Take the example of familial dysautonomia, a rare neurological disease where one mutation causes an extensive autonomous nervous system defect. These cells are difficult to procure and study. However, with the advent of iPSC technology, one can envision that a patient-specific iPSC would be generated and then differentiated into the affected cell type. This was accomplished in 2009 (Lee *et al.*, 2009) and the cells were successfully used to screen for drugs that could reduce the pathological

phenotypes. Several successful examples now exist using this approach (Robinton and Daley, 2012). For example, in a first-of-its-kind study, a humanized mouse model of sickle cell anemia had its disease phenotype rescued (Hanna *et al.*, 2007). Homologous recombination was used to repair the specific gene defect in iPSCs derived from the host, the corrected cells were subsequently programmed to hematopoietic progenitors and then transplanted back into the host. While several studies have used iPSCs derived from patients with specific diseases as a platform to then test drugs for efficacy, to date none of the identified drugs have been validated as working in the patients that had the original disease. While these scenarios are attractive, many of the hurdles that remain to be overcome are discussed below.

New Tools for Cell-Based Regenerative Therapy

There is tremendous excitement about the potential to use human stem cells for regenerative medicine. An impressive list of degenerative diseases and injuries would benefit from the ability to safely and correctly augment functional human tissues. This would consist of many examples including correction of degenerative neural diseases like Parkinson’s disease, Alzheimer’s disease, and dementias; repair of poor eyesight or immune deficiencies; and reversal of conditions like arthritis or organ failure. Current approaches to obtain cells for regenerative

medicine include adult stem cells, hESCs (after production, differentiation, and expansion), and, most recently, iPSCs (after production, differentiation, and expansion).

Each of these approaches have provided exciting and promising starting points but suffers from critical problems that limit their application. Currently, the only cells that are routinely being used in the clinic for regenerative medicine are adult stem cells. Several decades of success have proven the value of this approach with hematopoietic stem cells and skin stem cells. For example, bone marrow transplants or skin transplants have been used for decades to replenish a depleted hematopoietic system or to aid burn victims, respectively. However, despite the utility of this methodology, room for improvement exists. Indeed, adult stem cells therapy is often non-autologous and therefore necessitates immunosuppressive measures to prevent rejection of tissues. For example, patients with successful bone marrow transplants or skin transplants often face issues of graft versus host disease or host versus graft disease and require the need for lifelong administration of immunosuppressive therapy. Chronic flares of immunosuppressive issues can range from irritating to life threatening. Identification of other tissue-specific stem cells and their application to tissue repair will likely be limited by the same considerations. In contrast, the ability to use pluripotent cells from the patients' own body might be expected to avoid problems with immunosuppression often encountered with the use of adult multipotent stem cells taken from other patients.

Meanwhile, although under intense development, the successful use of an alternative source of cells, hESCs, has yet to be realized in the clinic. Aside from the ethical issues associated with destroying human embryos for the production of hESCs, similar immunosuppressive issues exist. In addition, issues of potential tumorigenicity related to the immortality and genetic instability of hESCs cause problems. Integrating differentiated cells into an already existing organ is not trivial. Additionally, the technically challenging and time-consuming process of generating ESCs does not have the potential to generate patient-specific differentiated tissues for acute injury. The proposed method to circumvent this problem is to create a bank of ESCs of different immune complement groups for off-the-shelf use. The first clinical trial utilizing hESC-derived cells to address a neurological defect was terminated midway through the trial for lack of funds. No adverse effects have been reported to date and the final results have not yet been reported. The first clinical trials using hESCs for eye repair have been initiated and are currently underway.

When the generation of human iPSCs was published in 2007 (Takahashi *et al.*, 2007), the excitement about the potential for these cells to advance regenerative medicine was obvious. However, several technical problems with the generation and use of iPSCs preclude their clinical use at the current time (Blasco *et al.*, 2011). The generation of iPSCs is a rare event and the introduction of exogenous DNA into human cells to activate the pluripotency pathways is not compatible with Federal Drug Administration (FDA) standards. Investigators are seeking cocktails of small molecules that will circumvent the FDA concern and at the same time generate high quality pluripotent iPSCs. Importantly, iPSCs exhibit genomic instability and immortality thus exhibiting a very real possibility of forming malignant tumors. In addition

to these challenges, current studies are documenting an 'epigenetic memory' that encourages the generated iPSCs to reset differentiated programs to that of the original tissue. For example, starting with fibroblasts, a mesodermal cell type, it is more difficult to generate ectodermal and endodermal derivatives than to generate mesodermal derivatives. This epigenetic instability has also been documented for multipotent cells derived from amniotic fluid (Rennie *et al.*, 2012). The iPSC technology in its present form cannot be used to introduce human cells back into the human body.

An unmet need in this field is to find a source of cells that can be used for regenerative medicine that will not be rejected by the patient's body and that will not carry exogenous reprogramming genes or an elevated threat of tumor formation. It is hypothesized that one of the reported endogenous pluripotent cell populations may be optimal to overcome the obstacles of immune rejection and rapid delivery. Using a person's own cells for regenerative medicine would circumvent the need for immunosuppressive drugs. Furthermore, the mortality, documented genomic stability, and nontumorigenicity of these recently described endogenous pluripotent cells would allay fears about high risk for spurious cancer formation. The greatest concerns, no matter which cell population eventually used, are for the safety of the patient and the fidelity of the regenerated tissue.

Clinical Trials and Contributions to Future Cell-Based Regenerative Therapy
